1 Introduction

This document describes least-squares minimization algorithms for fitting point sets by linear structures or quadratic structures. The organization is somewhat different from that of the previous version of the document. Modifications include the following.

- A section on the general formulation for nonlinear least-squares fitting is now available. The standard approach is to estimate parameters using numerical minimizers (Gauss–Newton or Levenberg–Marquardt).
- A new algorithm for fitting points by a circle, sphere or hypersphere is provided. The algorithm is non-iterative, so the computation time is bounded and small.
- In the previous version, the sections about fitting of points by ellipses or ellipsoids were severely lacking details and not useful for developing algorithms. Several algorithms are now provided for such fitting, including a general approach for fitting points by hyperellipsoids.
- The document for fitting points by a cylinder has been moved to this document. The website hyperlink to the cylinder document has been redirected to this document.
- A section has been added for fitting points by a single-sided cone.
- Pseudocode is now provided for each of the algorithms. Hyperlinks still exist for those algorithms implemented in the GTE source code.

Other documents using least-squares algorithms for fitting points with curve or surface structures are available at the website. The document for fitting points with a torus is new to the website (as of August 2018).

- Least-Squares Fitting of Data with Polynomials
- Least-Squares Fitting of Data with B-Spline Curves
- Least-Squares Reduction of B-Spline Curves
- Fitting 3D Data with a Helix
- Least-Squares Fitting of Data with B-Spline Surfaces
- Fitting 3D Data with a Torus

The document Least-Squares Fitting of Segments by Line or Plane describes a least-squares algorithm where the input is a set of line segments rather than a set of points. The output is a line (segments in \( n \) dimensions) or a plane (segments in 3 dimensions) or a hyperplane (segments in \( n \) dimensions).

2 The General Formulation for Nonlinear Least-Squares Fitting

Let \( F(p) = (F_0(p), F_1(p), \ldots, F_{n-1}(p)) \) be a vector-valued function of the parameters \( p = (p_0, p_1, \ldots, p_{m-1}) \). The nonlinear least-squares problem is to minimize the real-valued error function \( E(p) = |F(p)|^2 \).
Let \( J = dF/dp = [dF_r/dp_c] \) denote the Jacobian matrix, which is the matrix of first-order partial derivatives of the components of \( F \). The matrix has \( n \) rows and \( m \) columns, and the indexing \((r,c)\) refers to row \( r \) and column \( c \). A first-order approximation is

\[
F(p + d) \approx F(p) + J(p)d
\]

(1)

where \( d \) is an \( m \times 1 \) vector with small length. Consequently, an approximation to the error function is

\[
E(p + d) = ||F(p + d)||^2 = ||F(p) + J(p)d||^2
\]

(2)

The goal is to choose \( d \) to minimize \( ||F(p) + J(p)d||^2 \) and, hopefully, with \( E(p + d) < E(p) \). Choosing an initial \( p_0 \), the hope is that the algorithm generates a sequence \( p_i \) for which \( E(p_{i+1}) < E(p_i) \) and, in the limit, \( E(p_j) \) approaches the global minimum of \( E \). The algorithm is referred to as Gauss–Newton iteration.

For a single Gauss–Newton iteration, we need to choose \( d \) to minimize \( ||F(p) + J(p)d||^2 \) where \( p \) is fixed. This is a linear least-squares problem which can be formulated using the normal equations

\[
J^T(p)J(p)d = -J^T(p)F(p)
\]

(3)

The matrix \( J^TJ \) is positive semidefinite. If it is invertible, then

\[
d = -(J^T(p)J(p))^{-1}F(p)
\]

(4)

If it is not invertible, some other algorithm must be used to choose \( d \); one option is to use gradient descent for the step. A Cholesky decomposition can be used to solve the linear system.

During Gauss–Newton iteration, if \( E \) does not decrease for a step of the algorithm, one can modify the algorithm to Levenberg–Marquardt iteration. The idea is to smooth the linear system to

\[
(J^T(p)J(p) + \lambda I)d = -J^T(p)F(p)
\]

(5)

where \( I \) is the identity matrix of appropriate size and \( \lambda > 0 \) is the smoothing factor. The strategy for choosing the initial \( \lambda \) and how to adjust it as you compute iterations depends on the problem at hand.

For a more detailed discussion, see Gauss–Newton algorithm and Levenberg–Marquardt algorithm. Implementations of the Cholesky decomposition, Gauss–Newton method and Levenberg–Marquardt method in GTE can be found in CholeskyDecomposition.h, GaussNewtonMinimizer.h and LevenbergMarquardtMinimizer.h.

3 Affine Fitting of Points Using Height Fields

We have a set of measurements \( \{(X_i,h_i)\}_{i=1}^m \) for which \( X_i \in \mathbb{R}^n \) are sampled independent variables and \( h_i \in \mathbb{R} \) is a sampled dependent variable. The hypothesis is that \( h \) is related to \( X \) via an affine transformation \( h = A \cdot X + b \), where \( A \) is an \( n \times 1 \) vector of constants and \( b \) is a scalar constant. The goal is to estimate \( A \) and \( b \) from the samples. The choice of name \( h \) stresses that the measurement errors are in the direction of height above the plane containing the \( X \) measurements.

3.1 Fitting by a Line in 2 Dimensions

The measurements are \( \{(x_i,h_i)\}_{i=1}^m \) where \( x \) is an independent variable and \( h \) is a dependent variable. The affine transformation we want to estimate is \( h = ax + b \), where \( a \) and \( b \) are scalars. This defines a line that
best fits the samples in the sense that the sum of the squared errors between the \( h_i \) and the line values \( ax_i + b \) is minimized. Note that the error is measured only in the \( h \)-direction.

Define the error function for the least-squares minimization to be

\[
E(a, b) = \sum_{i=1}^{m} [(ax_i + b) - h_i]^2
\]  

(6)

This function is nonnegative and its graph is a paraboloid whose vertex occurs when the gradient satisfies

\[
\nabla E(a, b) = (\partial E/\partial a, \partial E/\partial b) = (0, 0)
\]

This leads to a system of two linear equations in \( a \) and \( b \) which can be easily solved. Precisely,

\[
\begin{align*}
0 &= \partial E/\partial a = 2 \sum_{i=1}^{m} [(ax_i + b) - h_i]x_i \\
0 &= \partial E/\partial b = 2 \sum_{i=1}^{m} [(ax_i + b) - h_i]
\end{align*}
\]

(7)

and so

\[
\begin{bmatrix}
\sum_{i=1}^{m} x_i^2 & \sum_{i=1}^{m} x_i \\
\sum_{i=1}^{m} x_i & \sum_{i=1}^{m} 1
\end{bmatrix}
\begin{bmatrix}
a \\
b
\end{bmatrix}
= 
\begin{bmatrix}
\sum_{i=1}^{m} x_i h_i \\
\sum_{i=1}^{m} h_i
\end{bmatrix}
\]  

(8)

The system is solved by standard numerical algorithms. If implemented directly, this formulation can lead to an ill-conditioned linear system. To avoid this, you should first compute the averages \( \bar{x} = (\sum_{i=1}^{m} x_i)/m \) and \( \bar{h} = (\sum_{i=1}^{m} h_i)/m \) and subtract them from the data. The fitted line is of the form \( \hat{h} - \bar{h} = \bar{a}(x - \bar{x}) + \bar{b} \).

The linear system of equations that determines the coefficients is

\[
\begin{bmatrix}
\sum_{i=1}^{m} (x_i - \bar{x})^2 & 0 \\
0 & m
\end{bmatrix}
\begin{bmatrix}
\bar{a} \\
\bar{b}
\end{bmatrix}
= 
\begin{bmatrix}
\sum_{i=1}^{m} (x_i - \bar{x})(h_i - \bar{h}) \\
0
\end{bmatrix}
\]

(9)

and has solution

\[
\bar{a} = \frac{\sum_{i=1}^{m} (x_i - \bar{x})(h_i - \bar{h})}{\sum_{i=1}^{m} (x_i - \bar{x})^2}, \quad \bar{b} = 0
\]

(10)

In terms of the original inputs, \( a = \bar{a} \) and \( b = \bar{h} - \bar{a}\bar{x} \).

3.1.1 Pseudocode for Fitting by a Line

Listing 1 contains pseudocode for fitting a height line to points in 2 dimensions.

**Listing 1.** Pseudocode for fitting a height line to points in 2 dimensions. The number of input points must be at least 2. The returned Boolean value is true as long as the numerator of equation (10) is positive; that is, when the points are not all the same point. An implementation in a slightly more general framework is ApprHeightLine2.h.

```cpp
bool FitHeightLine(int numPoints, Vector2 points[],
                   Real& barX, Real& barH, Real& barA)
{
    // Compute the mean of the points.
    Vector2 mean = ( 0, 0 );
    for (int i = 0; i < numPoints; ++i)
    {
        mean += points[i];
    }
    mean /= numPoints;
```
mean /= numPoints;

// Compute the linear system matrix and vector elements.
Real xxSum = 0, xhSum = 0;
for (int i = 0; i < numPoints; ++i)
{
    Vector2 diff = points[i] - mean;
    xxSum += diff[0] * diff[0];
    xhSum += diff[0] * diff[1];
    linear += diff[0] * diff[1];
}

// Solve the linear system.
if (xxSum > 0)
{
    // Compute the fitted line \( h(x) = \text{barH} + \text{barA} \cdot (x - \text{barX}) \).
    barX = mean[0];
    barH = mean[1];
    barA = linear / xxSum;
    return true;
}
else
{
    // The output is invalid. The points are all the same.
    barX = 0;
    barH = 0;
    barA = 0;
    return false;
}

3.2 Fitting by a Plane in 3 Dimensions

The measurements are \( \{(x_i, y_i, h_i)\}_{i=1}^m \) where \( x \) and \( y \) are independent variables and \( h \) is a dependent variable. The affine transformation we want to estimate is \( h = a_0 x + a_1 y + b \), where \( a_0, a_1 \) and \( b \) are scalars. This defines a plane that best fits the samples in the sense that the sum of the squared errors between the \( h_i \) and the plane values \( a_0 x_i + a_1 y_i + b \) is minimized. Note that the error is measured only in the \( h \)-direction.

Define the error function for the least-squares minimization to be

\[
E(a_0, a_1, b) = \sum_{i=1}^m [(a_0 x_i + a_1 y_i + b) - h_i]^2
\]  

This function is nonnegative and its graph is a hyperparaboloid whose vertex occurs when the gradient satisfies \( \nabla E(a_0, a_1, b) = (\partial E/\partial a_0, \partial E/\partial a_1, \partial E/\partial b) = (0, 0, 0) \). This leads to a system of three linear equations in \( a_0, a_1 \) and \( b \) which can be easily solved. Precisely,

\[
0 = \partial E/\partial a_0 = 2 \sum_{i=1}^m [(Ax_i + By_i + C) - z_i]x_i
\]
\[
0 = \partial E/\partial a_1 = 2 \sum_{i=1}^m [(Ax_i + By_i + C) - z_i]y_i
\]
\[
0 = \partial E/\partial b = 2 \sum_{i=1}^m [(Ax_i + By_i + C) - z_i]
\]

and so

\[
\begin{bmatrix}
\sum_{i=1}^m x_i^2 & \sum_{i=1}^m x_i y_i & \sum_{i=1}^m x_i \\
\sum_{i=1}^m x_i y_i & \sum_{i=1}^m y_i^2 & \sum_{i=1}^m y_i \\
\sum_{i=1}^m x_i & \sum_{i=1}^m y_i & \sum_{i=1}^m 1
\end{bmatrix}
\begin{bmatrix}
a_0 \\
a_1 \\
b
\end{bmatrix}
=
\begin{bmatrix}
\sum_{i=1}^m x_i h_i \\
\sum_{i=1}^m y_i h_i \\
\sum_{i=1}^m h_i
\end{bmatrix}
\]  

6
The solution is solved by standard numerical algorithms. If implemented directly, this formulation can lead to an ill-conditioned linear system. To avoid this, you should first compute the averages \( \bar{x} = (\sum_{i=1}^{m} x_i)/m, \)
\( \bar{y} = (\sum_{i=1}^{m} y_i)/m \) and \( \bar{h} = (\sum_{i=1}^{m} h_i)/m \) and subtract them from the data. The fitted plane is of the form
\( h - \bar{h} = a_0(x - \bar{x}) + a_1(y - \bar{y}) + b. \) The linear system of equations that determines the coefficients is
\[
\begin{bmatrix}
\ell_{00} & \ell_{01} & 0 \\
\ell_{01} & \ell_{11} & 0 \\
0 & 0 & m
\end{bmatrix}
\begin{bmatrix}
\tilde{a}_0 \\
\tilde{a}_1 \\
\tilde{b}
\end{bmatrix} =
\begin{bmatrix}
\sum_{i=1}^{m} (x_i - \bar{x})^2 & \sum_{i=1}^{m} (x_i - \bar{x})(y_i - \bar{y}) & 0 \\
\sum_{i=1}^{m} (x_i - \bar{x})(y_i - \bar{y}) & \sum_{i=1}^{m} (y_i - \bar{y})^2 & 0 \\
0 & 0 & m
\end{bmatrix}
\begin{bmatrix}
\tilde{a}_0 \\
\tilde{a}_1 \\
\tilde{b}
\end{bmatrix}
\]
and has solution
\[
\tilde{a}_0 = \frac{\ell_{11}r_0 - \ell_{01}r_1}{\ell_{00}\ell_{11} - \ell_{01}^2}, \quad \tilde{a}_1 = \frac{\ell_{00}r_1 - \ell_{01}r_0}{\ell_{00}\ell_{11} - \ell_{01}^2}, \quad \tilde{b} = 0
\]
In terms of the original inputs, \( a_0 = \tilde{a}_0, a_1 = \tilde{a}_1 \) and \( b = \bar{h} - \tilde{a}_0\bar{x} - \tilde{a}_1\bar{y}. \)

### 3.2.1 Pseudocode for Fitting by a Plane

Listing 2 contains pseudocode for fitting a height plane to points in 3 dimensions.

```cpp
bool FitHeightPlane(int numPoints, Vector3 points[], Real& barX, Real& barY, Real& barH, Real& barA0, Real& barA1) {
    // Compute the mean of the points.
    Vector3 mean = {0, 0, 0};
    for (int i = 0; i < numPoints; ++i) {
        mean += points[i];
    }
    mean /= numPoints;

    // Compute the linear system matrix and vector elements.
    Real xxSum = 0, xySum = 0, xhSum = 0, yySum = 0, yhSum = 0;
    for (int i = 0; i < numPoints; ++i) {
        Vector3 diff = points[i] - mean;
        xxSum += diff[0] * diff[0];
        xySum += diff[0] * diff[1];
        xhSum += diff[0] * diff[2];
        yySum += diff[1] * diff[1];
        yhSum += diff[1] * diff[2];
    }

    // Solve the linear system.
    Real det = xxSum * yySum - xySum * xhSum;
    if (det != 0) {
        // Compute the fitted plane h(x,y) = barH + barA0 * (x - barX) + barA1 * (y - barY).
    }
}
```
3.3 Fitting by a Hyperplane in \( n + 1 \) Dimensions

The measurements are \( \{(X_i, h_i)\}_{i=1}^m \) where the \( n \) components of \( X \) are independent variables and \( h \) is a dependent variable. The affine transformation we want to estimate is \( h = A \cdot X + b \), where \( A \) is an \( n \times 1 \) vector of constants and \( b \) is a scalar constant. This defines a hyperplane that best fits the samples in the sense that the sum of the squared errors between the \( h_i \) and the hyperplane values \( A \cdot X_i + b \) is minimized.

Note that the error is measured only in the \( h \)-direction.

Define the error function for the least-squares minimization to be

\[
E(A, b) = \sum_{i=1}^m [(A \cdot X_i + b) - h_i]^2
\]  

This function is nonnegative and its graph is a hyperparaboloid whose vertex occurs when the gradient satisfies \( \nabla E(A, b) = (\partial E/\partial A, \partial E/\partial b) = (0, 0) \). This leads to a system of \( n + 1 \) linear equations in \( A \) and \( b \) which can be easily solved. Precisely,

\[
0 = \frac{\partial E}{\partial A} = 2 \sum_{i=1}^m [(A \cdot X_i + b) - h_i]X_i
\]

\[
0 = \frac{\partial E}{\partial b} = 2 \sum_{i=1}^m [(A \cdot X_i + b) - h_i]
\]

and so

\[
\begin{bmatrix}
\sum_{i=1}^m X_iX_i^T & \sum_{i=1}^m X_i \\
\sum_{i=1}^m X_i^T & \sum_{i=1}^m 1
\end{bmatrix}
\begin{bmatrix}
A \\
b
\end{bmatrix} =
\begin{bmatrix}
\sum_{i=1}^m h_iX_i \\
\sum_{i=1}^m h_i
\end{bmatrix}
\]  

(18)

The solution is solved by standard numerical algorithms. If implemented directly, this formulation can lead to an ill-conditioned linear system. To avoid this, you should first compute the averages \( \bar{X} = (\sum_{i=1}^m X_i)/m \) and \( \bar{h} = (\sum_{i=1}^m h_i)/m \) and subtract them from the data. The fitted hyperplane is of the form \( \bar{h} - h = \bar{A} \cdot (X - \bar{X}) + \bar{b} \). The linear system of equations that determines the coefficients is

\[
\begin{bmatrix}
\sum_{i=1}^m (X_i - \bar{X}) (X_i - \bar{X})^T \\
0^T
\end{bmatrix}
\begin{bmatrix}
\bar{A} \\
\bar{b}
\end{bmatrix} =
\begin{bmatrix}
\sum_{i=1}^m (h_i - \bar{h}) (X_i - \bar{X}) \\
0
\end{bmatrix}
\]  

(19)
and has solution

\[
A = \left( \sum_{i=1}^{m} (X_i - \bar{X})(X_i - \bar{X})^T \right)^{-1} \left( \sum_{i=1}^{m} (h_i - \bar{h})(X_i - \bar{X}) \right), \quad \bar{b} = 0
\]  

(20)

In terms of the original inputs, \(A = \bar{A}\) and \(b = \bar{h} - \bar{A} \cdot \bar{X}\).

### 3.3.1 Pseudocode for Fitting a Hyperplane

Listing 3 contains pseudocode for fitting a height hyperplane to points in \(n + 1\) dimensions.

---

**Listing 3.** Pseudocode for fitting a height hyperplane to points in \(n + 1\) dimensions. The number of input points must be at least \(n\). The returned Boolean value is true as long as the matrix of the linear system has nonzero determinant.

```cpp
bool FitHeightHyperplane(int numPoints, Vector<n + 1> points[], Vector<n> & barX, Real & barH, Vector<n> & barA)
{
    // Compute the mean of the points.
    Vector<n + 1> mean = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        mean += points[i];
    }
    mean /= numPoints;
    // Compute the linear system matrix and vector elements. The function
    // Vector<n> Head<n>(Vector<n + 1> V) returns (V[0],...,V[n-1]).
    Matrix<n,n> L = Matrix<n,n>::ZERO;
    Vector<n> R = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        Vector<n + 1> diff = points[i] - mean;
        Vector<n> XminusBarX = Head<n>(diff);
        Real HminusBarH = diff[n];
        L += OuterProduct(XminusBarX, XminusBarX);
        // (X[i]−barX[i])*(X[i]−barX[i))^T
        R += HminusBarH * XminusBarX;
    }
    // Solve the linear system.
    Real det = Determinant(L);
    if (det != 0)
    {
        // Compute the fitted plane h(X) = barH + Dot(barA, X - barX).
        barX = Head<n>(mean);
        barH = mean[n];
        barA = SolveLinearSystem(L, R); // solve L*barA = R
        return true;
    }
    else
    {
        // The output is invalid. The points appear not to live on a
        // hyperplane; they might live in an affine subspace of dimension
        // smaller than n.
        barX = Vector<n>::ZERO;
        barH = 0;
        barA = Vector<n>::ZERO;
        return false;
    }
}
```
4 Affine Fitting of Points Using Orthogonal Regression

We have a set of measurements \{X_i\}_{i=1}^m for which \(X_i \in \mathbb{R}^n\) are sampled independent variables. The hypothesis is that the points are sampled from a \(k\)-dimensional affine subspace in \(n\)-dimensional space. Such a space is referred to as a \(k\)-dimensional flat. The classic cases include fitting a line to points in \(n\) dimensions and fitting a plane to points in 3 dimensions. The latter is a special case of fitting a hyperplane, an \((n-1)\)-dimensional flat, to points in \(n\) dimensions.

In the height-field fitting algorithms, the least-squares errors were measured in a specified direction (the height direction). An alternative is to measure the errors in the perpendicular direction to the purported affine subspace. This approach is referred to as orthogonal regression.

4.1 Fitting by a Line [1 Dimension]

The algorithm may be applied to sample points \(\{X_i\}_{i=1}^m\) in any dimension \(n\). Let the line have origin \(A\) and unit-length direction \(D\), both \(n \times 1\) vectors. Define \(Y_i = X_i - A\), which can be written as \(Y_i = (D \cdot Y_i)D + D_i^\perp\) where \(D_i^\perp\) is the perpendicular vector from \(X_i\) to its projection on the line. The squared length of this vector is \(|D_i^\perp|^2 = |Y_i - d_iD|^2\). The error function for the least-squares minimization is

\[ E(A, D) = \sum_{i=1}^m |D_i^\perp|^2 \]  

(21)

Two alternate forms for this function are

\[ E(A, D) = \sum_{i=1}^m (Y_i^T (I - DD^T) Y_i) \]

(22)

\[ E(A, D) = D^T \left( \sum_{i=1}^m (Y_i \cdot Y_i)I - Y_i Y_i^T \right) D = D^T M D \]

where \(M\) is a positive semidefinite symmetric matrix that depends on \(A\) and the \(Y_i\) but not in \(D\). Compute the derivative of equation (21) with respect to \(A\) to obtain

\[ \frac{\partial E}{\partial A} = -2 \left[ I - DD^T \right] \sum_{i=1}^m Y_i \]  

(23)

At a minimum value of \(E\), it is necessary that this derivative is zero, which it is when \(\sum_{i=1}^m Y_i = 0\), implying \(A = (1/m) \sum_{i=1}^m X_i\), the average of the sample points. In fact there are infinitely many solutions, \(A + sD\), for any scalar \(s\). This is simply a statement that \(A\) is a point on the best-fit line, but any other point on the line may serve as the origin for that line.

Equation (22) is a quadratic form \(D^T M D\) whose minimum is the smallest eigenvalue of \(M\), computed using standard eigensystem solvers. A corresponding unit length eigenvector \(D\) completes our construction of the least-squares line. The covariance matrix of the input points is \(C = \sum_{i=1}^m Y_i Y_i^T\). Defining \(\delta = \sum_{i=1}^m Y_i Y_i^T\), we see that \(M = \delta I - C\), where \(I\) is the identity matrix. Therefore, \(M\) and \(C\) have the same eigenspaces. The eigenspace corresponding to the minimum eigenvalue of \(M\) is the same as the eigenspace corresponding to the maximum eigenvalue of \(C\). In an implementation, it is sufficient to process \(C\) and avoid the additional cost to compute \(M\).
4.1.1 Pseudocode for the General Case

Listing 4 contains pseudocode for fitting a line to points in $n$ dimensions with $n \geq 2$.

```c
bool FitOrthogonalLine(int numPoints, Vector<n> points[],
    Vector<n>& origin, Vector<n>& direction)
{
    // Compute the mean of the points.
    Vector<n> mean = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    { mean += points[i]; }
    mean /= numPoints;

    // Compute the covariance matrix of the points.
    Matrix<n,n> C = Matrix<n,n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    { Vector<n> diff = points[i] - mean;
        C += OuterProduct(diff, diff); // diff \cdot diff^T
    }

    // Compute the eigenvalues and eigenvectors of C, where the eigenvalues are sorted
    // in nondecreasing order (eigenvalues[0] <= eigenvalues[1] <= ...).
    Real eigenvalues[n];
    Vector<n> eigenvectors[n];
    SolveEigensystem(C, eigenvalues, eigenvectors);

    // Set the output information.
    origin = mean;
    direction = eigenvectors[n-1];

    // The fitted line is unique when the maximum eigenvalue has multiplicity 1.
    return eigenvalues[n-2] < eigenvalues[n-1];
}
```

Specializations for 2 and 3 dimensions are simple, computing only the upper-triangular elements of $C$ and passing them to specialized eigensolvers for 2 and 3 dimensions. Implementations are ApprOrthogonalLine2.h and ApprOrthogonalLine3.h.

4.2 Fitting by a Hyperplane $[(n-1)\text{ Dimensions}]$

The algorithm may be applied to sample points $\{X_i\}_{i=1}^m$ in any dimension $n$. Let the hyperplane be defined implicitly by $N \cdot (X - A) = 0$, where $N$ is a unit-length normal to the hyperplane and $A$ is a point on the hyperplane. Define $Y_i = X_i - A$, which can be written as $Y_i = (N \cdot Y_i)N + N_i^\perp$ where $N_i^\perp$ is a vector that is perpendicular to $N$. The squared length of the projection of $Y_i$ onto the normal line for the hyperplane is $(N \cdot Y_i)^2$. The error function for the least-squares minimization is $E(A, N) = \sum_{i=1}^m (N \cdot Y_i)^2$. Two alternate forms for this function are

$$E(A, N) = \sum_{i=1}^m (Y_i^T (NN^T) Y_i)$$

(24)
and

\[ E(A, N) = N^T \left( \sum_{i=1}^{m} Y_i Y_i^T \right) N = N^T C N \]  

(25)

where \( C = \sum_{i=1}^{m} Y_i Y_i^T \) is the covariance matrix of the \( Y_i \).

Compute the derivative of equation (24) with respect to \( A \) to obtain

\[ \frac{\partial E}{\partial A} = 2 \left( N N^T \right) \sum_{i=1}^{m} Y_i \]  

(26)

At a minimum value of \( E \), it is necessary that this derivative is zero, which it is when \( \sum_{i=1}^{m} Y_i = 0 \), implying \( A = (1/m) \sum_{i=1}^{m} X_i \), the average of the sample points. In fact there are infinitely many solutions, \( A + W \), where \( W \) is any vector perpendicular to \( N \). This is simply a statement that the average is on the best-fit hyperplane, but any other point on the hyperplane may serve as the origin for that hyperplane.

Equation (25) is a quadratic form \( N^T C N \) whose minimum is the smallest eigenvalue of \( C \), computed using standard eigensystem solvers. A corresponding unit-length eigenvector \( N \) completes our construction of the least-squares hyperplane.

### 4.2.1 Pseudocode for the General Case

Listing 5 contains pseudocode for fitting a hyperplane to points in \( n \) dimensions with \( n \geq 3 \).

**Listing 5.** Pseudocode for fitting a line to points in \( n \) dimensions using orthogonal regression. The number of input points must be at least \( n \). The returned Boolean value is true as long as the covariance matrix of the linear system has a 1-dimensional eigenspace for the minimum eigenvalue of the covariance matrix.

```csharp
bool FitOrthogonalHyperplane(int numPoints, Vector<n> points[], Vector<n>& origin, Vector<n>& normal)
{
    // Compute the mean of the points.
    Vector<n> mean = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        mean += points[i];
    }
    mean /= numPoints;

    // Compute the covariance matrix of the points.
    Matrix<n,n> C = Matrix<n,n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        Vector<n> diff = points[i] - mean;
        C += OuterProduct(diff, diff); // diff * diff^T
    }

    // Compute the eigenvalues and eigenvectors of M, where the eigenvalues are sorted
    // in nondecreasing order (eigenvalues[0] <= eigenvalues[1] <= ...).
    Real eigenvalues[n];
    Vector<n> eigenvectors[n];
    SolveEigensystem(C, eigenvalues, eigenvectors);

    // Set the output information.
    origin = mean;
    normal = eigenvectors[0];

    // The fitted hyperplane is unique when the minimum eigenvalue has multiplicity 1.
    return eigenvalues[0] < eigenvalues[1];
}
```
A specialization for 3 dimensions is simple, computing only the upper-triangular elements of $C$ and passing them to a specialized eigensolver for 3 dimensions. An implementation is ApprOrthogonalPlane3.h.

### 4.3 Fitting by a Flat \([k\) Dimensions]\)

Orthogonal regression to fit \(n\)-dimensional points by a line or by a hyperplane can be generalized to fitting by an affine subspace called a \(k\)-dimensional flat, where you may choose \(k\) such that \(1 \leq k \leq n - 1\). A line is a 1-flat and a hyperplane is an \((n - 1)\)-flat.

For dimension \(n = 3\), we fit with flats that are either lines \((k = 1)\) or planes \((k = 2)\). For dimensions \(n \geq 4\) and flat dimensions \(1 \leq k \leq n - 1\), the generalization of orthogonal regression is the following. The bases mentioned here are for the linear portion of the affine subspace; that is, the basis vectors are relative to an origin at a point \(A\). The flat has an orthonormal basis \(\{F_j\}_{j=1}^k\) and the orthogonal complement has an orthonormal basis \(\{P_j\}_{j=1}^{n-k}\). The union of the two bases is an orthonormal basis for \(\mathbb{R}^n\). Any input point \(X_i\), \(1 \leq i \leq m\), can be represented by

\[
X_i = A + \sum_{j=1}^{k} f_{ij} F_j + \sum_{j=1}^{n-k} p_{ij} P_j = \left( A + \sum_{j=1}^{k} f_{ij} F_j \right) + \left( \sum_{j=1}^{n-k} p_{ij} P_j \right)
\]

(27)

The left-parenthesized term is the portion of \(X_i\) that lives in the flat and the right-parenthesized is the portion that is the deviation of \(X_i\) from the flat. The least-squares problem is about choosing the two bases so that the sum of squared lengths of the deviations is as small as possible.

Define \(Y_i = X_i - A\). The basis coefficients are \(f_{ij} = F_j \cdot Y_i\) and \(p_{ij} = P_j \cdot Y_i\). The squared length of the deviation is \(\sum_{j=1}^{n-k} p_{ij}^2\). The error function for the least-squares minimization is the sum of the squared lengths for all inputs, \(E = \sum_{i=1}^{m} \sum_{j=1}^{n-k} p_{ij}^2\). Two alternate forms for this function are

\[
E(A, P_1, \ldots, P_{n-k}) = \sum_{i=1}^{m} Y_i^T \left( \sum_{j=1}^{n-k} P_j P_j^T \right) Y_i
\]

(28)

and

\[
E(A, P_1, \ldots, P_{n-k}) = \sum_{j=1}^{n-k} P_j^T \left( \sum_{i=1}^{m} Y_i Y_i^T \right) P_j = \sum_{j=1}^{n-k} P_j^T C P_j
\]

(29)

where \(C = \sum_{i=1}^{m} Y_i Y_i^T\).

Compute the derivative of equation (28) with respect to \(A\) to obtain

\[
\frac{\partial E}{\partial A} = 2 \left( \sum_{j=1}^{n-k} P_j P_j^T \right) \sum_{i=1}^{m} Y_i
\]

(30)

At a minimum value of \(E\), it is necessary that this derivative is zero, which it is when \(\sum_{i=1}^{m} Y_i = 0\), implying \(A = (1/m) \sum_{i=1}^{m} X_i\), the average of the sample points. In fact there are infinitely many solutions, \(A + W\), where \(W\) is any vector in the orthogonal complement of the subspace spanned by the \(P_j\); this subspace is...
the one spanned by the $F_j$. This is simply a statement that the average is on the best-fit flat, but any other point on the flat may serve as the origin for that flat. Because we are choosing $A$ to be the average of the input points, the matrix $C$ is the covariance matrix for the input points.

The last term in equation (29) is a sum of quadratic forms involving the matrix $C$ and the vectors $P_j$ that are a basis (unit length, mutually perpendicular). The minimum value of the quadratic form is the smallest eigenvalue $\lambda_1$ of $C$, so we may choose $P_1$ to be a unit-length eigenvector of $C$ corresponding to $\lambda_1$. We must choose $P_2$ to be unit length and perpendicular to $P_1$. If the eigenspace for $\lambda_1$ is 1-dimensional, the next smallest value we can attain by the quadratic form is the smallest eigenvalue $\lambda_2$ for which $\lambda_1 < \lambda_2$. $P_2$ is chosen to be a corresponding unit-length eigenvector. However, if $\lambda_1$ has an eigenspace of dimension larger than 1, we can choose $P_2$ in that eigenspace but which is perpendicular to $P_1$.

Generally, let $\{\lambda_\ell\}_{\ell=1}^r$ be the $r$ distinct eigenvalues of the covariance matrix $C$; we know $1 \leq r \leq n$ and $\lambda_1 < \lambda_2 < \cdots < \lambda_r$. Let the dimension of the eigenspace for $\lambda_\ell$ be $d_\ell$; we know that $\sum_{\ell=1}^r d_\ell = n$. List the eigenvalues and eigenvectors in order of increasing eigenvalue, including repeated values,

$$
\begin{pmatrix}
\lambda_1 & \cdots & \lambda_1 \\
V_1^1 & \cdots & V_1^{d_1} \\
\end{pmatrix} \quad \begin{pmatrix}
\lambda_2 & \cdots & \lambda_2 \\
V_2^1 & \cdots & V_2^{d_2} \\
\end{pmatrix} \quad \cdots \quad \begin{pmatrix}
\lambda_r & \cdots & \lambda_r \\
V_r^1 & \cdots & V_r^{d_r} \\
\end{pmatrix}
$$

(31)

The list has $n$ items. The eigenvalue $d_\ell$ has an eigenspace with orthonormal basis $\{V_\ell^j\}_{j=1}^{d_\ell}$. In this list, choose the first $k$ eigenvectors to be $P_1$ through $P_k$ and choose the last $n - k$ eigenvectors to be $F_1$ through $F_{n-k}$.

It is possible that one (or more) of the $P_j$ and one (or more) of the $F_j$ are in the eigenspace for the same eigenvalue. In this case, the fitted flat is not unique, and one should re-examine the choice of dimension $k$ for the fitted flat. This is analogous to the following situations in dimension $n = 3$:

- The input points are nearly collinear but you are trying to fit those points with a plane. The covariance matrix likely has two distinct eigenvalues $\lambda_1 < \lambda_2$ with $d_1 = 2$ and $d_2 = 1$. The basis vectors are $P_1 = V_1^1$, $F_1 = V_2^1$, and $F_2 = V_2^2$. The first two of these are from the same eigenspace.

- The input points are spread out over a portion of a plane (and are not nearly collinear) but you are trying to fit those points with a line. The covariance matrix likely has two distinct eigenvalues $\lambda_1 < \lambda_2$ with $d_1 = 1$ and $d_2 = 2$. The basis vectors are $P_1 = V_1^1$, $P_2 = V_1^2$, and $F_1 = V_2^1$. The last two of these are from the same eigenspace.

- The input points are not well fit by a flat of any dimension. For example, your input points are uniformly distributed over a sphere. The covariance matrix likely has one distinct eigenvalue $\lambda_1$ of multiplicity $d_1 = 3$. Neither a line nor a plane is a good fit to the input points—in either case, a $P$-vector and an $F$-vector are in the same eigenspace.

The computational algorithm is to compute the average $A$ and covariance matrix of the points. Use an eigensolver whose output eigenvalues are sorted in nondecreasing order. Choose the $F_j$ to be the last $n - k$ eigenvectors output by the eigensolver.

### 4.3.1 Pseudocode for the General Case

Listing 6 contains pseudocode for fitting a $k$-dimensional flat to points in $n$-dimensions where $n \geq 2$ and $1 \leq k \leq n - 1$. 

14
Listing 6. Pseudocode for fitting a $k$-dimensional flat to points in $n$ dimensions using orthogonal regression. The number of input points must be at least $k + 1$. The returned Boolean value is true as long as the covariance matrix of the linear system has a basis of eigenvectors sorted by nondecreasing eigenvalues for which the following holds. The subsbasis that spans the linear space of the flat and the subsbasis that spans the orthogonal complement of the linear space of the flat do not both contain basis vectors from the same eigenspace.

```cpp
bool FitOrthogonalFlat(int numPoints, Vector<n> points[],
   Vector<n>& origin, Vector<k>& flatBasis, Vector<n-k>& complementBasis)
{
    // Compute the mean of the points.
    Vector<n> mean = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        mean += points[i];
    }
    mean /= numPoints;

    // Compute the covariance matrix of the points.
    Matrix<n,n> C = Matrix<n,n>::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        Vector<n> diff = points[i] - mean;
        C += OuterProduct(diff, diff); // diff * diff^T
    }

    // Compute the eigenvalues and eigenvectors of M, where the eigenvalues are sorted
    // in nondecreasing order (eigenvalues[0] <= eigenvalues[1] <= ...).
    Real eigenvalues[n];
    Vector<n> eigenvectors[n];
    SolveEigensystem(C, eigenvalues, eigenvectors);

    // Set the output information. The basis for the fitted flat corresponds
    // to the largest variances and the basis for the complement of the fitted
    // flat corresponds to the smallest variances.
    origin = mean;
    for (int i = 0; i < n - k; ++i)
    {
        complementBasis[i] = eigenvectors[i];
    }
    for (int i = 0; i < k; ++i)
    {
        flatBasis[i] = eigenvectors[n - k + i];
    }

    // The fitted flat and its complement do not have vectors from the same eigenspace.
    return eigenvalues[n - k - 1] < eigenvalues[n - k];
}
```

In the special case of fitting with a line ($k = 1$), the line direction is the only element in `flatBasis`. In the special case of fitting with a hyperplane ($k = n - 1$), the hyperplane normal is the only element in `complementBasis`.

5 Fitting a Hypersphere to Points

The classic cases are fitting 2-dimensional points by circles and 3-dimensional points by spheres. In $n$-dimensions, the objects are called hyperspheres, defined implicitly by the quadratic equation $|C - X|^2 = r^2$, where $C$ is the center and $r$ is the radius. Three algorithms are presented for fitting points by hyperspheres.
5.1 Fitting Using Differences of Lengths and Radius

The sample points are \( \{X_i\}_{i=1}^m \). The least-squares error function involves the squares of differences between lengths and radius,

\[
E(C, r) = \sum_{i=1}^m (|C - X_i| - r)^2
\]

The minimization is based on computing points where the gradient of \( E \) is zero. The partial derivative with respect to \( r \) is

\[
\frac{\partial E}{\partial r} = -2 \sum_{i=1}^m (|C - X_i| - r)
\]

Setting the derivative equal to zero and solving for the radius,

\[
r = \frac{1}{m} \sum_{i=1}^m |C - X_i|
\]

which says that the radius is the average of the distances from the sample points to the center \( C \). The partial derivative with respect to \( C \) is

\[
\frac{\partial E}{\partial C} = 2 \sum_{i=1}^m (|C - X_i| - r) \frac{\partial (C - X_i)}{\partial C} = 2 \sum_{i=1}^m (|C - X_i| - r) \frac{C - X_i}{|C - X_i|}
\]

Setting the derivative equal to zero and solving for the center,

\[
C = \frac{1}{m} \sum_{i=1}^m X_i + r \frac{1}{m} \sum_{i=1}^m \frac{C - X_i}{|C - X_i|} = \frac{1}{m} \sum_{i=1}^m X_i + \left( \frac{1}{m} \sum_{i=1}^m |C - X_i| \right) \left( \frac{1}{m} \sum_{i=1}^m \frac{C - X_i}{|C - X_i|} \right)
\]

The average of the samples is \( \bar{X} \). Define length \( L_i = |C - X_i| \); the average of the lengths is \( \bar{L} \). Define unit-length vector \( U_i = (C - X_i)/|C - X_i| \); the average of the unit-length vectors is \( \bar{U} \). Equation (36) becomes

\[
C = \bar{X} + \bar{L} \bar{U} =: F(C)
\]

were the last equality defines the vector-valued function \( F \). The function depends on the independent variable \( C \) because both \( \bar{L} \) and \( \bar{U} \) depend on \( C \). Fixed-point iteration can be applied to solve equation (37),

\[
C_{i+1} = F(C_i), \quad i \geq 0
\]

Depending on the distribution of the samples, it is possible to choose a different initial guess for \( C_0 \) that (hopefully) leads to faster convergence.

5.1.1 Pseudocode for the General Case

Listing 7 contains pseudocode for fitting a hypersphere to points. The case \( n = 2 \) is for circles and the case \( n = 3 \) is for spheres.
Listing 7. Fitting a hypersphere to points using least squares based on squared differences of lengths and radius. If you want the incoming hypersphere center to be the initial guess for the center, set inputCenterIsIni-
tialGuess; otherwise, the initial guess is computed to be the average of the samples. The maximum number
of iterations is also specified. The returned function value is the number of iterations used.

```c
int FitHypersphere(int numPoints, Vector<n> X[], int maxIterations, bool inputCenterIsInitialGuess,
          Vector<n>& center, Real& radius)
{
    // Compute the average of the data points.
    Vector<n> averageX = X[0];
    for (int i = 1; i < numPoints; ++i)
    {
        averageX += X[i];
    }
    averageX /= numPoints;
    // The initial guess for the center is either the incoming center of the
    // average of the sample points.
    if (!inputCenterIsInitialGuess)
    {
        center = averageX;
    }
    int iteration;
    for (iteration = 0; iteration < maxIterations; ++iteration)
    {
        // Update the estimate for the center.
        Vector<n> previousCenter = center;
        // Compute average L and average U.
        Real averageL = 0;
        Vector<n> averageU = Vector<n>::ZERO;
        for (int i = 0; i < numPoints; ++i)
        {
            Vector<n> CmXi = center - X[i];
            Real length = Length(CmXi);
            if (length > 0)
            {
                averageL += length;
                averageU += CmXi / length;
            }
        }
        averageL /= numPoints;
        averageU /= numPoints;
        center = averageX + averageL * averageU;
        radius = averageL;
        // Test for convergence.
        if (center == previousCenter)
        {
            break;
        }
    }
    return ++iteration;
}
```

The convergence test uses an exact equality, that the previous center $C'$ and the current center $C$ are the
same. In practice you might want to specify a small $\varepsilon > 0$ and instead exit when $|C - C'| \leq \varepsilon$.

Specializations for 2 and 3 dimensions have the same implementation as the general case. Implementations
are ApprCircle2.h and ApprSphere3.h.
5.2 Fitting Using Differences of Squared Lengths and Squared Radius

The sample points are \( \{X_i\}_{i=1}^m \). The least-squares error function involves the squares of differences between squared lengths and squared radius,

\[
E(C, r^2) = \sum_{i=1}^{m} (|C - X_i|^2 - r^2)^2
\]  

(39)

The minimization is based on computing points where the gradient of \( E \) is zero. The partial derivative with respect to \( r^2 \) is

\[
\frac{\partial E}{\partial r^2} = -2 \sum_{i=1}^{m} (|C - X_i|^2 - r^2)
\]  

(40)

Define \( \Delta_i = C - X_i \). Setting the derivative to zero and solving for the squared radius,

\[
r^2 = \frac{1}{m} \sum_{i=1}^{m} |C - X_i|^2 = \frac{1}{m} \sum_{i=1}^{m} \Delta_i^T \Delta_i
\]  

(41)

which says that the squared radius is the average of the squared distances from the sample points to the center \( C \). The partial derivative with respect to \( C \) is

\[
\frac{\partial E}{\partial C} = 4 \sum_{i=1}^{m} (|C - X_i|^2 - r^2) (C - X_i) = 4 \sum_{i=1}^{m} (\Delta_i^T \Delta_i - r^2) \Delta_i
\]  

(42)

Setting this to zero, the center and radius must satisfy

\[
\sum_{i=1}^{m} (\Delta_i^T \Delta_i - r^2) \Delta_i = 0
\]  

(43)

Expanding the squared lengths,

\[
\Delta_i^T \Delta_i = |C|^2 - 2C^T X_i + |X_i|^2
\]  

(44)

Substituting into equation (41),

\[
r^2 = |C|^2 - 2C^T \left( \frac{1}{m} \sum_{i=1}^{m} X_i \right) + \frac{1}{m} \sum_{i=1}^{m} |X_i|^2 = |C|^2 - 2C^T A + \frac{1}{m} \sum_{i=1}^{m} |X_i|^2
\]  

(45)

where \( A = (\sum_{i=1}^{m} X_i) / m \) is the average of the samples. Define \( Y_i = X_i - A \). Some algebra will show that

\[
\Delta_i^T \Delta_i - r^2 = \frac{1}{m} \sum_{i=1}^{m} |X_i|^2 - \frac{1}{m} \sum_{j=1}^{m} |X_j|^2
\]  

(46)

where the last equality defines \( B_i \). Equation (43) becomes

\[
0 = \sum_{i=1}^{m} \left( \Delta_i^T \Delta_i - r^2 \right) \Delta_i
\]

\[
= \sum_{i=1}^{m} \left( -2(C - A)^T Y_i + B_i \right) ((C - A) - Y_i)
\]

\[
= ((C - A)^T \sum_{i=1}^{m} Y_i) (C - A) + 2 \left( \sum_{i=1}^{m} Y_i Y_i^T \right) (C - A) + (\sum_{i=1}^{m} B_i) (C - A) - \sum_{i=1}^{m} B_i Y_i
\]  

(47)
It is easily shown that $\sum_{i=1}^{m} Y_i = 0$ and $\sum_{i=1}^{m} B_i = 0$; therefore,

$$0 = 2 \left( \sum_{i=1}^{m} Y_i Y_i^T \right) (C - A) - \sum_{i=1}^{m} \left( Y_i^T Y_i \right) Y_i \quad (48)$$

The least-squares center is obtained by solving the previous equation,

$$C = A + \frac{1}{2} \left( \sum_{i=1}^{m} Y Y_i^T \right)^{-1} \sum_{i=1}^{m} \left( Y_i^T Y_i \right) Y_i \quad (49)$$

### 5.2.1 Pseudocode for the General Case

Listing 8 contains pseudocode for fitting a hypersphere to points. The case $n = 2$ is for circles and the case $n = 3$ is for spheres.

**Listing 8.** Fitting a hypersphere to points using least squares based on squared differences of squared lengths and square radius. The algorithm requires inverting the covariance matrix. If the matrix is invertible, the output center and radius are valid and the function returns true. If the matrix is not invertible, the function returns false, and the center and radius are invalid (but set to zero so at least they are initialized).

```cpp
bool FitHypersphere(int numPoints, Vector<n> X[], Vector<n>& center, Real& radius) {
    // Compute the average of the data points.
    Vector<n> A = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i) {
        A += X[i];
    }
    A /= numPoints;
    // Compute the covariance matrix M of the Y[i] = X[i] - A and the right-hand side R of the linear system M*(C-A) = R.
    Matrix<n, n> M = Matrix<n, n>::ZERO;
    Vector<n> R = Vector<n>::ZERO;
    for (int i = 0; i < numPoints; ++i) {
        Vector<n> Y = X[i] - A;
        Matrix<n, n> YYT = OuterProduct(Y, Y); // Y^T*Y
        Real YTY = Dot(Y, Y); // Y^T*Y
        M += YYT;
        R += YTY * Y;
    }
    R /= 2;
    // Solve the linear system M*(C-A) = R for the center C. The function bool Solve(M, R, S) tries to solve the linear system M*S = R. If M is invertible, the function returns true and S is the solution. If M is not invertible, the function returns false and S is invalid.
    Vector<n> CmA;
    if (Solve(M, R, CmA)) {
        center = A + CmA;
        Real rsqr = 0;
        for (int i = 0; i < numPoints; ++i) {
            Vector<n> delta = X[i] - center;
            rsqr += Dot(delta, delta);
        }
        center += CmA / numPoints;
        radius = sqrt(rsqr);
    }
    return false;
}
```
5.2.2 Pseudocode for Circles

Listing 9 is a specialization of Listing 8 for circles in 2 dimensions. The matrix inversion requires only computing the upper-triangular part of the covariance matrix and uses cofactors for inversion.

Listing 9. Fitting a circle to points using least squares based on squared differences of squared lengths and square radius. The algorithm requires inverting the covariance matrix. If the matrix is invertible, the output center and radius are valid and the function returns true. If the matrix is not invertible, the function returns false, and the center and radius are invalid (but set to zero so at least they are initialized).

```cpp
bool FitCircle(int numPoints, Vector2 X[], Vector2& center, Real& radius)
{
    // Compute the average of the data points.
    Vector2 A = { 0, 0 };
    for (int i = 0; i < numPoints; ++i)
    {
        A += X[i];
    }
    A /= numPoints;

    // Compute the covariance matrix M of the Y[i] = X[i]−A and the right-hand side R of the linear
    // system M*(C−A) = R.
    Real M00 = 0, M01 = 0, M11 = 0;
    Vector2 R = { 0, 0 };
    for (int i = 0; i < numPoints; ++i)
    {
        Vector2 Y = X[i]−A;
        Real Y0Y0 = Y[0]*Y[0], Y0Y1 = Y[0]*Y[1], Y1Y1 = Y[1]*Y[1];
        M00 += Y0Y0; M01 += Y0Y1; M11 += Y1Y1;
        R += (Y0Y0 + Y1Y1) * Y;
    }
    R /= 2;

    // Solve the linear system M*(C−A) = R for the center C.
    Real det = M00 * M11 − M01 * M01;
    if (det != 0)
    {
        Vector2 delta = X[i]−center;
        Real rsqr = 0;
        for (int i = 0; i < numPoints; ++i)
        {
            rsqr += Dot(delta, delta);
        }
        radius = sqrt(rsqr);
        return true;
    }
    else
    {
        center = { 0, 0 };
    }
}
```
radius = 0;
return false;
}

5.2.3 Pseudocode for Spheres

Listing 10 is a specialization of Listing 8 for spheres in 3 dimensions. The matrix inversion requires only computing the upper-triangular part of the covariance matrix and uses cofactors for inversion.

Listing 10. Fitting a sphere to points using least squares based on squared differences of squared lengths and square radius. The algorithm requires inverting the covariance matrix. If the matrix is invertible, the output center and radius are valid and the function returns true. If the matrix is not invertible, the function returns false, and the center and radius are invalid (but set to zero so at least they are initialized).

```cpp
bool FitSphere(int numPoints, Vector3 X[], Vector3& center, Real& radius) {
    // Compute the average of the data points.
    Vector3 A = {0, 0, 0};
    for (int i = 0; i < numPoints; ++i) {
        A += X[i];
    }
    A /= numPoints;
    // Compute the covariance matrix M of the Y[i] = X[i]−A and the right-hand side R of the linear system M*(C−A) = R.
    Real M00 = 0, M01 = 0, M02 = 0, M11 = 0, M12 = 0, M22 = 0;
    Vector3 R = {0, 0, 0};
    for (int i = 0; i < numPoints; ++i) {
        Vector2 Y = X[i]−A;
        Real Y0Y0 = Y[0] * Y[0], Y0Y1 = Y[0] * Y[1], Y0Y2 = Y[0] * Y[2];
        M00 += Y0Y0; M01 += Y0Y1; M02 += Y0Y2;
        M11 += Y1Y1; M12 += Y1Y2; M22 += Y2Y2;
    }
    R /= 2;
    // Solve the linear system M*(C−A) = R for the center C.
    Real cof00 = M11 * M22 − M12 * M21;
    Real cof01 = M02 * M12 − M01 * M22;
    Real cof02 = M01 * M12 − M02 * M11;
    Real cof11 = M00 * cof00 + M01 * cof01 + M02 * cof02;
    Real cof12 = M00 * cof01 + M01 * cof02 + M02 * cof00;
    Real cof22 = M00 * cof02 + M01 * cof12 + M02 * cof11;
    Real det = cof00 * cof11 * cof22 + cof01 * cof12 * cof20 + cof02 * cof10 * cof21 - cof00 * cof12 * cof21 - cof01 * cof10 * cof22 - cof02 * cof11 * cof20;
    if (det != 0) {
        Real cof11 = M00 * M22 − M02 * M20;
        Real cof12 = M00 * M12 − M01 * M20;
        Real cof22 = M00 * M11 − M01 * M10;
        center[0] = A[0] + (cof00 * R[0] + cof01 * R[1] + cof02 * R[2]) / det;
        Real rsqr = 0;
        for (int i = 0; i < numPoints; ++i) {
            Vector3 delta = X[i]−center;
            rsqr += Dot(delta, delta);
        }
        radius = sqrt(rsqr);
        return true;
    }
    return false;
}
```
5.3 Fitting the Coefficients of a Quadratic Equation

The general quadratic equation that represents a hypersphere in \( n \) dimensions is

\[
b_0 + b_1 \cdot X + b_2 |X|^2 = 0
\]  

(50)

where \( b_0 \) and \( b_2 \neq 0 \) are scalar constants and \( b_1 \) is an \( n \times 1 \) vector of scalars. Define

\[
\mathbf{b} = \begin{bmatrix} b_0 \\ b_1 \\ b_2 \end{bmatrix}, \quad \mathbf{V} = \begin{bmatrix} 1 \\ X \\ |X|^2 \end{bmatrix}
\]

(51)

which are both \((n + 2) \times 1\) vectors. The quadratic equation is \( \mathbf{b} \cdot \mathbf{V} = 0 \). Because \( \mathbf{b} \) is not zero, we can remove a degree of freedom by requiring \( |\mathbf{b}| = 1 \).

Given samples \( \{X_i\}_{i=1}^m \), we can estimate the constants using a least-squares algorithm where the error function is

\[
E(\mathbf{b}) = \sum_{i=1}^m (\mathbf{b} \cdot \mathbf{V}_i)^2 = \mathbf{b}^T \left( \sum_{i=1}^m \mathbf{V}_i \mathbf{V}_i^T \right) \mathbf{b} = \mathbf{b}^T \mathbf{V} \mathbf{b}
\]

(52)

where as a tuple, \( \mathbf{V}_i = (1, X_i, |X_i|^2) \), and where \( \mathbf{V} = \sum_{i=1}^m \mathbf{V}_i \mathbf{V}_i^T \) is a positive semidefinite matrix (symmetric, eigenvalues are nonnegative). The error function is minimized by a unit-length eigenvector \( \mathbf{b} \) that corresponds to the minimum eigenvalue of \( \mathbf{V} \). The equation (50) is factored into

\[
\left| X + \frac{\mathbf{b}_1}{2b_2} \right|^2 = \left| \frac{\mathbf{b}_1}{2b_2} \right|^2 - \frac{b_0}{b_2}
\]

(53)

from which we see that the hypersphere center is \( \mathbf{C} = -\mathbf{b}_1/(2b_2) \) and the radius is \( r = \sqrt{(|\mathbf{b}_1|^2 - 4b_0b_2)/(4b_2^2)} \).

As is typical of these types of problems, it is better to subtract translate the samples by their average to obtain numerical robustness when computing with floating-point arithmetic. Define \( \mathbf{A} = (\sum_{i=1}^m X_i) \) and \( \mathbf{Y}_i = X_i - \mathbf{A} \). Equation (50) becomes

\[
f_0 + f_1 \cdot \mathbf{Y} + f_2 |\mathbf{Y}|^2 = 0
\]

(54)

where

\[
\begin{bmatrix} b_0 \\ b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} f_0 - f_1 \cdot \mathbf{A} + f_2 |\mathbf{A}|^2 \\ f_1 - 2f_2 \mathbf{A} \\ f_2 \end{bmatrix} = \begin{bmatrix} 1 & -\mathbf{A}^T & |\mathbf{A}|^2 \end{bmatrix} \begin{bmatrix} f_0 \\ 0 \\ 0 \end{bmatrix} = \mathbf{Mf}
\]

(55)
with $I$ the $n \times n$ identity matrix and $\mathbf{0}$ the $n \times 1$ zero vector. The last equality defines the $(n+2) \times (n+2)$ upper-triangular matrix $M$ and the $(n+2) \times 1$ vector $f$. The error function is now

$$E(f) = \mathbf{b}^T V \mathbf{b} = (Rf)^T V (Rf) = f^T (R^T V R) f = f^T W f$$

where the last equation defines the $(n+2) \times (n+2)$ upper-triangular matrix $M$ and the $(n+2) \times 1$ vector $f$. The error function is now

$$E(f) = b^T V b = (Rf)^T V (Rf) = f^T (R^T V R) f = f^T W f$$

where the last equality defines the positive semidefinite matrix $W$. Observe that

$$W = R^T \left( \sum_{i=1}^{m} V_i V_i^T \right) R = \sum_{i=1}^{m} (R^T V_i) (R^T V_i)^T = \sum_{i=1}^{m} W_i W_i^T$$

where

$$W_i = R^T V_i = \begin{bmatrix} 1 & 0^T & 0 \\ -A & I & 0 \\ |A|^2 & -2A^T & 1 \end{bmatrix} \begin{bmatrix} 1 \\ X_i \\ |X_i|^2 \end{bmatrix} = \begin{bmatrix} 1 \\ X_i - A \\ |X_i - A|^2 \end{bmatrix}$$

Therefore, we can subtract $A$ from the samples, compute the matrix $W$, extract its eigenvector $f$ corresponding to its minimum eigenvalue, compute $b = Rf$ and then the center and radius using equation (53). The matrix $W$ written as a block matrix and divided by the number of points $m$ to keep the numerical intermediate values on the order of the sample values is

$$W = \begin{bmatrix} 1 & 0^T & \frac{1}{m} \sum_{i=1}^{m} |Y_i|^2 \\ 0 & \frac{1}{m} \sum_{i=1}^{m} Y_i Y_i^T & \frac{1}{m} \sum_{i=1}^{m} |Y_i|^2 Y_i \\ \frac{1}{m} \sum_{i=1}^{m} |Y_i|^2 & \frac{1}{m} \sum_{i=1}^{m} |Y_i|^2 Y_i & \frac{1}{m} |Y_i|^4 \end{bmatrix}$$

### 5.3.1 Pseudocode for the General Case

Listing 11 contains pseudocode for fitting a hypersphere to points. The case $n = 2$ is for circles and the case $n = 3$ is for spheres.

```cpp
bool FitHypersphere(int numPoints, Vector<n> X[], Vector<n>& center, Real& radius) {
  // Compute the average of the data points and the squared length of the average.
  Vector<n> A = Vector<n>::ZERO;
  for (int i = 0; i < numPoints; ++i)
    { A += X[i]; }
  A /= numPoints;
  Real sqLenA = Dot(A, A);
  // Compute the components of W. Block(r, c, rsize, csize) is an accessor to the block
  // whose upper-left location is (r, c) and whose size is rsize-by-csize. The indices
  // r and c are zero-based.
  Matrix<n + 2, n + 2> W = Matrix<n + 2, n + 2>::ZERO;
```
for (int i = 0; i < numPoints; ++i)
{
    Vector<n> Y = X[i] - A;
    Matrix<n, n> YYT = OuterProduct(Y, Y); // Y*Transpose(Y)
    Real YTY = Dot(Y, Y); // Transpose(Y)*Y
    Vector YYTY = YTY * Y;
    Real YYTYTY = YYTY * YYTY;
    W.Block(0, 0, 1, 1) += 1;
    W.Block(0, n + 1, 1, 1) += YTY;
    W.Block(1, 1, n + 1, 1) += YYT;
    W.Block(1, n + 1, n + 1, 1) += YYTY;
    W.Block(n + 1, 0, 1, 1) += YTY;
    W.Block(n + 1, 1, 1, n + 1) += YYTY;
    W.Block(n + 1, n + 1, 1, 1) += YYTYTY;
}
W /= numPoints;

Listing 12. Fitting a circle to points using least squares to fit the coefficients of a quadratic equation defining the hypersphere. The algorithm requires computing the squared radius in terms of the components of an eigenvector. For samples not really distributed well on a hypersphere, the purported squared radius might be negative. The function returns true when that computation is nonnegative or false when it is negative.

bool FitCircle(int numPoints, Vector2 X[], Vector2& center, Real& radius)
{
    // Compute the average of the data points and the squared length of the average.
    Vector2 A = {0, 0};
    for (int i = 0; i < numPoints; ++i)
{  
A += X[i];  
}
A /= numPoints;
Real sqLenA = Dot(A, A);

// Compute the upper-triangular components of W.
Matrix4x4 W = Matrix4x4::ZERO;
for (int i = 0; i < numPoints; ++i)
{
  Vector2 Y = X[i] - A;
  Real Y0Y0 = Y[0] * Y[0], Y0Y1 = Y[0] * Y[1], Y1Y1 = Y[1] * Y[1];
  Real RR = Y0Y0 + Y1Y1, RRRR = RR * RR;
  Real Y0RR = Y0 * RR, Y1RR = Y1 * RR;
  W(0, 3) += RR;
  W(1, 1) += Y0Y0;
  W(1, 2) += Y0Y1;
  W(1, 3) += Y0RR;
  W(2, 2) += Y1Y1;
  W(2, 3) += Y1RR;
  W(3, 3) += RRRR;
}
W /= numPoints;
W(0, 0) = 1;

// Fill in the lower-triangular components of W.
W(3, 0) = W(0, 3);
W(2, 1) = W(1, 2);
W(3, 1) = W(1, 3);
W(3, 2) = W(2, 3);

// Compute the eigenvalues and eigenvectors of M, where the eigenvalues are sorted
// in nondecreasing order
Real eigenvalues[4];
Vector4 eigenvectors[4];
SolveEigensystem(W, eigenvalues, eigenvectors);
Real f0 = eigenvectors[0][0];
Vector2 f1 = ( eigenvectors[0][1], eigenvectors[0][2] );
Real f2 = eigenvectors[0][3];
Real b0 = f0 - Dot(f1, A) + f2 * sqLenA;
Vector2 b1 = f1 - 2 * f2 * A;
Real b2 = f2;
if (b2 != 0)
{
  Real discr = Dot(b1, b1) - 4 * b0 * b2;
  if (discr >= 0)
  {
    center = -b1 / (2 * b2);
    radius = sqrt(discr / (4 * b2 + b2));
    return true;
  }
}

center = Vector2::ZERO;
radius = 0;
return false;

5.3.3 Pseudocode for Spheres

Listing 13 contains pseudocode for fitting a sphere to points.
Listing 13. Fitting a sphere to points using least squares to fit the coefficients of a quadratic equation defining the hypersphere. The algorithm requires computing the squared radius in terms of the components of an eigenvector. For samples not really distributed well on a hypersphere, the purported squared radius might be negative. The function returns `true` when that computation is nonnegative or `false` when it is negative.

```cpp
bool FitSphere(int numPoints, Vector3 X[], Vector3& center, Real& radius)
{
    // Compute the average of the data points and the squared length of the average.
    Vector3 A = { 0, 0, 0 };  
    for (int i = 0; i < numPoints; ++i)
    {
        A += X[i];  
    }
    A /= numPoints;
    Real sqrLenA = Dot(A, A);

    // Compute the upper-triangular components of W.
    Matrix5x5 W = Matrix5x5::ZERO;
    for (int i = 0; i < numPoints; ++i)
    {
        Vector3 Y = X[i] - A;
        Real Y0Y0 = Y[0] * Y[0], Y0Y1 = Y[0] * Y[1], Y1Y1 = Y[1] * Y[1];
        Real RR = Y0Y0 + Y1Y1 + Y2Y2, RRRR = RR * RR;
        Real Y0RR = Y0 * RR, Y1RR = Y1 * RR, Y2RR = Y2 * RR;
        W(0, 4) += RR;
        W(1, 1) += Y0Y0;
        W(1, 2) += Y0Y1;
        W(1, 3) += Y0Y2;
        W(1, 4) += Y0RR;
        W(2, 2) += Y1Y1;
        W(2, 3) += Y1Y2;
        W(2, 4) += Y1RR;
        W(3, 3) += Y2Y2;
        W(3, 4) += Y2RR;
        W(4, 4) += RRRR;
    }
    W /= numPoints;
    W(0, 0) = 1;

    // Fill in the lower-triangular components of W.
    W(4, 0) = W(0, 4);
    W(2, 1) = W(1, 2);
    W(3, 1) = W(1, 3);
    W(4, 1) = W(1, 4);
    W(3, 2) = W(2, 3);
    W(4, 2) = W(2, 4);
    W(4, 3) = W(3, 4);

    // Compute the eigenvalues and eigenvectors of M, where the eigenvalues are sorted
    // in nondecreasing order
    Real eigenvalues[5];
    Vector5 eigenvectors[5];
    SolveEigensystem(W, eigenvalues, eigenvectors);
    Real f0 = eigenvectors[0][0];
    Vector3 f1 = { eigenvectors[0][1], eigenvectors[0][2], eigenvectors[0][3] };
    Real f2 = eigenvectors[0][4];
    Real b0 = f0 - Dot(f1, A) + f2 * sqrLenA;
    Vector3 b1 = f1 - 2 * f2 * A;
    Real b2 = f2;
    if (b2 != 0)
    {
        Real discr = Dot(b1, b1) - 4 * b0 * b2;
        if (discr >= 0)
        {
            center = -b1 / (2 * b2);
        }
    }
}
```
6 Fitting a Hyperellipsoid to Points

The classic cases are fitting 2-dimensional points by ellipses and 3-dimensional points by ellipsoids. In n-dimensions, the objects are called hyperellipsoids, defined implicitly by the quadratic equation

\[(X - C)^T S (X - C) = 1\]  

(60)

The center of the hyperellipsoid is the \(n \times 1\) vector \(C\), the \(n \times n\) matrix \(S\) is positive definite, and the \(n \times 1\) vector \(X\) is any point on the hyperellipsoid. The matrix \(S\) can be factored using an eigendecomposition, \(S = RDR^T\), where \(R\) is an \(n \times n\) rotation matrix whose \(n \times 1\) columns are unit-length vectors \(U_i\) for \(0 \leq i < n\) that form a right-handed orthonormal basis. The \(n \times n\) matrix \(D\) is diagonal with diagonal elements \(d_i = 1/e_i^2\) for \(0 \leq i < n\). The extent \(e_i > 0\) is the distance from \(C\) to the two extreme points of the hyperellipsoid in the direction \(U_i\). The matrix \(S\) can be expressed as

\[S = \sum_{i=0}^{n-1} \frac{U_i U_i^T}{e_i^2} = \sum_{i=0}^{n-1} \frac{V_i V_i^T}{e_i^2 |V_i|^2}\]  

(61)

The second equality uses vectors \(V_i\) that are not necessarily unit length, which is useful when robust computations require arbitrary precision arithmetic for exact results. The length of \(V_i\) is not necessary to compute; rather, we compute \(|V_i|^2 = V_i \cdot V_i\) to eliminate floating-point rounding errors that occur when normalizing \(V_i\) to obtain \(U_i\).

Let the samples be \(\{X_i\}_{i=1}^m\). A nonlinear least-squares error function used for the fitting is

\[E(C, S) = \frac{1}{m} \sum_{i=1}^{m} \left[(X_i - C)^T S (X_i - C) - 1\right]^2\]  

(62)

An iterative algorithm is presented for locating the parameters \(C\) and \(S\). It is based on gradient descent, which requires derivative computations. The symmetric matrix \(S\) has \(n(n + 1)/2\) parameters consisting of the upper-triangular part of the matrix. The vector \(C\) has \(n\) parameters.

Define \(\Delta_i = X_i - C\). The first-order derivative of \(E\) with respect to the center is

\[\frac{\partial E}{\partial C} = -\frac{2}{m} \sum_{i=1}^{m} \left(\Delta_i^T S \Delta_i - 1\right) S \Delta_i\]  

(63)

The first-order derivative of \(E\) with respect to the component \(s_{rc}\) of \(S\) is

\[\frac{\partial E}{\partial s_{rc}} = \begin{cases} \frac{2}{m} \sum_{i=1}^{m} \left(\Delta_i^T S \Delta_i - 1\right) \Delta_i^T B_{rr} \Delta_i, & r = c \\ \frac{2}{m} \sum_{i=1}^{m} \left(\Delta_i^T S \Delta_i - 1\right) \Delta_i^T (B_{rc} + B_{cr}) \Delta_i, & r \neq c \end{cases}\]  

(64)
where \( B_{rc} \) is the matrix whose elements are all 0 except for the entry in row \( r \) and column \( c \) which is 1.

The algorithm uses a 2-Step gradient step whereby the center and matrix are alternately updated.

### 6.1 Updating the Estimate of the Center

Given initial guesses \( C \) and \( S \) for the hyperellipsoid, the center can be updated to \( C' = C + tN \) for \( t \geq 0 \), where \( N = -\partial E/\partial C \) is the negative of the gradient of \( E \) in the \( C \) direction at the initial guess. This is one step of the gradient descent algorithm, searching in the direction of largest decrease of \( E \) in the \( C \) parameter. Define the function

\[
g(t) = E(C + tN, S) = \frac{1}{m} \sum_{i=1}^{m} \left[ (tN - \Delta_i)^T S (tN - \Delta_i) - 1 \right]^2
\]

where \( c = N^T S N, b_i = N^T S \Delta_i \) and \( a_i = \Delta_i^T S \Delta_i - 1 \). Some algebra will show that

\[
g(t) = g_0 + g_1 t + g_2 t^2 + g_3 t^3 + g_4 t^4
\]

where

\[
g_0 = \frac{1}{m} \sum_{i=1}^{m} a_i^2, \quad g_1 = -\frac{4}{m} \sum_{i=1}^{m} a_i b_i, \quad g_2 = \frac{4}{m} \sum_{i=1}^{m} b_i^2 + \frac{2c}{m} \sum_{i=1}^{m} a_i, \quad g_3 = -\frac{4c}{m} \sum_{i=1}^{m} b_i, \quad g_4 = c^2
\]

The derivative is \( g'(t) = g_1 + 2g_2 t + 3g_3 t^2 + 4g_4 t^3 \).

Observe that \( g(t) \geq 0 \) because it is the nonnegative error function evaluated along a line in the domain. In practice, one never expects the minimum of \( E \) to be zero, so \( g(t) > 0 \). In particular, \( g(0) > 0 \). The search is in the largest direction of decrease for \( E \) along any line through the initial guess, which implies \( g'(0) \leq 0 \). If \( g'(0) = 0 \) with \( g(0) \) a local minimum, the line search terminates. If \( g'(0) < 0 \), notice that the coefficient \( g_4 > 0 \), so \( g'(\infty) = \infty \). These conditions guarantee that \( g'(t) \) has at least one root for \( t > 0 \). Of all such roots, let \( T \) be the root for which \( g(T) \) is the smallest value. It must be the case that \( g(T) < g(0) \), so in fact \( E(C, S) < E(C + tN) \) and the updated estimate for the center is \( C' = C + tN \).

### 6.2 Updating the Estimate of the Matrix

Given initial guesses \( C \) and \( S \) for the hyperellipsoid, the matrix can be updated to \( S' = S + tN \) for \( t \geq 0 \), where \( N = -\partial E/\partial S \) is the negative of the gradient of \( E \) in the \( S \) direction at the initial guess. This is another step of the gradient descent algorithm, searching in the direction of largest decrease of \( E \) in the \( S \) parameter. Define the function

\[
h(t) = E(C, S + tN)
\]

where

\[
h_0 = \frac{1}{m} \sum_{i=1}^{m} \left[ \Delta_i^T (S + tN) \Delta_i - 1 \right]^2
\]

and

\[
h_1 = \frac{1}{m} \sum_{i=1}^{m} \left[ (\Delta_i^T N \Delta_i) t + (\Delta_i^T S \Delta_i - 1) \right]^2
\]

and

\[
h_0 = \frac{1}{m} \sum_{i=1}^{m} (b_i t + a_i)^2
\]

28
where \( b_i = \Delta_i^T N \Delta_i \) and \( a_i = \Delta_i^T S \Delta_i - 1 \). Some algebra will show that
\[
h(t) = h_0 + h_1 t + h_2 t^2
\]
(69)

where
\[
h_0 = \frac{1}{m} \sum_{i=1}^{m} a_i^2, \quad h_1 = \frac{2}{m} \sum_{i=1}^{m} a_i b_i, \quad h_2 = \frac{1}{m} \sum_{i=1}^{m} b_i^2
\]
(70)

The derivative is \( h'(t) = h_1 + 2h_2 t \).

Observe that \( h(t) \geq 0 \) because it is the nonnegative error function evaluated along a line in the domain. In practice, one never expects the minimum of \( E \) to be zero, so \( h(t) > 0 \). In particular, \( h(0) > 0 \). The search is in the largest direction of decrease for \( E \) along any line through the initial guess, which implies \( h'(0) \leq 0 \). If \( h'(0) = 0 \) with \( h(0) \) a local minimum, the line search terminates. If \( h'(0) < 0 \), notice that the coefficient \( h_2 > 0 \), so \( h'(\infty) = \infty \). These conditions guarantee that \( h'(t) \) has at least one root for \( t > 0 \). Of all such roots, let \( T \) be the root for which \( h(T) \) is the smallest value. It must be the case that \( h(T) < h(0) \).

We need to ensure that \( S + TN \) is positive definite. If it is positive definite, the updated estimate for the matrix is \( S' = S + TN \). If it is not positive definite, the root is halved and \( S' = S + (T/2)N \) is tested for positive definiteness. If it is still not positive definite, the halving is repeated until a power \( p > 0 \) is obtained for which \( S'' = S + (T/2^p)N \) is positive definite.

The test for positive definiteness uses Sylvester’s criterion which says that \( S \) is positive definite if all of its leading principal minors are positive. The minors are determinants of the upper-left \( 1 \times 1 \) block, the upper-left \( 2 \times 2 \) block, and so on through the determinant of \( S \) itself. For \( n = 2 \), \( S \) is positive definite when
\[
\det \begin{bmatrix} s_{00} \end{bmatrix} > 0, \quad \det \begin{bmatrix} s_{00} & s_{01} \\ s_{01} & s_{11} \end{bmatrix} > 0
\]
(71)

For \( n = 3 \), \( S \) is positive definite when
\[
\det \begin{bmatrix} s_{00} \end{bmatrix} > 0, \quad \det \begin{bmatrix} s_{00} & s_{01} \\ s_{01} & s_{11} \end{bmatrix} > 0, \quad \det \begin{bmatrix} s_{00} & s_{01} & s_{02} \\ s_{01} & s_{11} & s_{12} \\ s_{02} & s_{12} & s_{22} \end{bmatrix} > 0
\]
(72)

### 6.3 Pseudocode for the Algorithm

The initial guesses for \( C \) and \( S \) can be provided by the caller or they can be estimated internally. In the Geometric Tools implementation, the internal algorithm is to compute an oriented bounding box for the input points and use the box center as the initial \( C \). The initial \( S \) is compute from the box axes and box extents using equation (61). Listing 14 contains pseudocode for the algorithm.

---

**Listing 14.** Pseudocode for fitting a hyperellipsoid to points. The number of iterations is specified by the caller. The function can be called multiple times, the first time allowing the internal estimate of the initial center and matrix. A subsequent call uses the hyperellipsoid from the previous call. The function returns the error function value that can be monitored by the caller to decide whether or not to make subsequent calls.

        hyperellipsoid.extent[i] = 1 / sqrt(eigenvalue[i]);
    }
    return error;
}

7 Fitting a Cylinder to 3D Points

This document describes an algorithm for fitting a set of 3D points with a cylinder. The assumption is that
the underlying data is modeled by a cylinder and that errors have caused the points not to be exactly on
the cylinder. You could very well try to fit a random set of points, but the algorithm is not guaranteed to
produce a meaningful solution.

7.1 Representation of a Cylinder

An infinite cylinder is specified by an axis containing a point \( C \) and having unit-length direction \( W \). The
radius of the cylinder is \( r > 0 \). Two more unit-length vectors \( U \) and \( V \) may be defined so that \( \{U, V, W\} \)
is a right-handed orthonormal set; that is, all vectors are unit-length, mutually perpendicular, and with $U \times V = W$, $V \times W = U$, and $W \times U = V$. Any point $X$ may be written uniquely as

$$X = C + y_0 U + y_1 V + y_2 W = C + RY$$

(73)

where $R$ is a rotation matrix whose columns are $U$, $V$, and $W$ and where $Y$ is a column vector whose rows are $y_0$, $y_1$, and $y_2$. To be on the cylinder, we need

$$r^2 = y_0^2 + y_1^2$$

$$= (U \cdot (X - C))^2 + (V \cdot (X - C))^2$$

$$= (X - C)^T (UU^T + VV^T)(X - C)$$

$$= (X - C)^T (I - WW^T)(X - C)$$

(74)

where $I$ is the identity matrix. Because the unit-length vectors form an orthonormal set, it is necessary that $I = UU^T + VV^T + WW^T$. A finite cylinder is obtained by bounding the points in the axis direction,

$$|y_2| = |W \cdot (X - C)| \leq h/2$$

(75)

where $h > 0$ is the height of the cylinder.

### 7.2 The Least-Squares Error Function

Let $\{X_i\}_{i=1}^n$ be the input point set. An error function for a cylinder fit based on Equation (74) is

$$E(r^2, C, W) = \sum_{i=1}^n [F(X_i; r^2, C, W)]^2 = \sum_{i=1}^n \left( (X_i - C)^T (I - WW^T)(X_i - C) - r^2 \right)^2$$

(76)

where the cylinder axis is a line containing point $C$ and having unit-length direction $W$ and the cylinder radius is $r$. Thus, the error function involves 6 parameters: 1 for the squared radius $r^2$, 3 for the point $C$, and 2 for the unit-length direction $W$. These parameters form the 6-tuple $q$ in the generic discussion presented previously.

For numerical robustness, it is advisable to subtract the sample mean $A = (\sum_{i=1}^n X_i)/n$ from the samples, $X_i \leftarrow X_i - A$. This preconditioning is assumed in the mathematical derivations to follow, in which case $\sum_{i=1}^n X_i = 0$.

In the following discussion, define

$$P = I - WW^T, \quad r_i^2 = (C - X_i)^T P(C - X_i)$$

(77)

The matrix $P$ represents a projection onto a plane with normal $W$, so $P^2 = P$ and depends only on the direction $W$. The term $r_i^2$ depends on the center $C$ and the direction $W$. The error function is written concisely as $E = \sum_{i=1}^n (r_i^2 - r^2)^2$. 

31
7.3 An Equation for the Radius

The partial derivative of the error function with respect to the squared radius is \( \partial E/\partial r^2 = -2 \sum_{i=1}^{n} (r_i^2 - r^2) \). Setting this to zero, we have the constraint

\[
0 = \sum_{i=1}^{n} (r_i^2 - r^2)
\]

which leads to

\[
r^2 = \frac{1}{n} \sum_{i=1}^{n} r_i^2
\]

Thus, the squared radius is the average of the squared distances of the projections of \( X_i - C \) onto a plane containing \( C \) and having normal \( W \). The right-hand side depends on the parameters \( C \) and \( W \).

Observe that

\[
r_i^2 - r^2 = r_i^2 - \frac{1}{n} \sum_{j=1}^{n} r_j^2
\]

\[
= (C - X_i)^T P(C - X_i) - \frac{1}{n} \sum_{j=1}^{n} (C - X_j)^T P(C - X_j)
\]

\[
= C^T PC - 2X_i^T PC + X_i^T PX_i - \frac{1}{n} \sum_{j=1}^{n} (C^T PC - 2X_j^T PC + X_j^T PX_j)
\]

\[
= C^T PC - 2X_i^T PC + X_i^T PX_i - C^T PC + \frac{2}{n} \sum_{j=1}^{n} X_j^T PX_j
\]

\[
= \left( \frac{1}{n} \sum_{j=1}^{n} X_j^T - X_i^T \right) 2PC + \left( X_i^T PX_i - \frac{1}{n} \sum_{j=1}^{n} X_j^T PX_j \right)
\]

\[
= -X_i^T 2PC + \left( X_i^T PX_i - \frac{1}{n} \sum_{j=1}^{n} X_j^T PX_j \right)
\]

The last equality is based on the precondition \( \sum_{j=1}^{n} X_j = 0 \).

7.4 An Equation for the Center

The partial derivative with respect to the center is \( \partial E/\partial C = -4 \sum_{i=1}^{n} (r_i^2 - r^2) P(X_i - C) \). Setting this to zero, we have the constraint

\[
0 = \sum_{i=1}^{n} (r_i^2 - r^2) P(X_i - C)
\]

\[
= \sum_{i=1}^{n} (r_i^2 - r^2) PX_i - \left[ \sum_{i=1}^{n} (r_i^2 - r^2) \right] PC
\]

\[
= \sum_{i=1}^{n} (r_i^2 - r^2) PX_i
\]

where the last equality is a consequence of Equation (78). Multiply equation (80) by \( PX_i \), sum over \( i \), and use equation (81) to obtain

\[
0 = -2P \left( \sum_{i=1}^{n} X_i X_i^T \right) PC + \sum_{i=1}^{n} \left( X_i^T PX_i \right) PX_i - \left( \frac{1}{n} \sum_{j=1}^{n} X_j^T PX_j \right) P \sum_{i=1}^{n} X_i
\]

\[
= -2P \left( \sum_{i=1}^{n} X_i X_i^T \right) PC + \sum_{i=1}^{n} \left( X_i^T PX_i \right) PX_i
\]

where the last equality is based on the precondition \( \sum_{i=1}^{n} X_i = 0 \). We wish to solve this equation for \( C \), but observe that \( C + tW \) are valid centers for all \( t \). It is sufficient to compute a center that has no component
in the $W$-direction; that is, we may construct a point for which $C = PC$. It suffices to solve Equation (82) for $PC$ written as the linear system $A(PC) = B/2$ where

$$A = P \left( \frac{1}{n} \sum_{i=1}^{n} X_i X_i^T \right) P, \quad B = \frac{1}{n} \sum_{i=1}^{n} \left( X_i^T P X_i \right) P X_i$$

(83)

The projection matrix is symmetric, $P = P^T$, a condition that leads to the right-hand side of the equation defining $A$. We have used $P = P^2$ to introduce an additional $P$ factor, $X_i^T P X_i = X_i^T P^2 X_i = X_i^T P T P X_i$, which leads to the right-hand side of the equation defining $B$.

The matrix $A$ is singular because the projection matrix $P$ is singular, so we cannot directly invert $A$ to solve the equation. The linear system involves terms that live only in the plane perpendicular to $W$, so in fact the linear system reduces to two equations in two unknowns in the projection space and is solvable as long as the coefficient matrix is invertible.

Choose $U$ and $V$ so that $\{U, V, W\}$ is a right-handed orthonormal set; then $P X_i = \mu_i U + \nu_i V$ and $PC = k_0 U + k_1 V$, where $\mu_i = U \cdot X_i$, $\nu_i = V \cdot X_i$, $k_0 = U \cdot PC$, and $k_1 = V \cdot PC$. The matrix $A$ becomes

$$A = \left( \frac{1}{n} \sum_{i=1}^{n} \mu_i^2 \right) U U^T + \left( \frac{1}{n} \sum_{i=1}^{n} \mu_i \nu_i \right) (U V^T + V U^T) + \left( \frac{1}{n} \sum_{i=1}^{n} \nu_i^2 \right) V V^T$$

(84)

and the vector $B$ becomes

$$B = \frac{1}{n} \sum_{i=1}^{n} (\mu_i^2 + \nu_i^2) \left( \mu_i U + \nu_i V \right)$$

(85)

The vector $A(PC)$ becomes

$$A(PC) = \left( \frac{k_0}{n} \sum_{i=1}^{n} \mu_i^2 + \frac{k_1}{n} \sum_{i=1}^{n} \mu_i \nu_i \right) U + \left( \frac{k_0}{n} \sum_{i=1}^{n} \mu_i \nu_i + \frac{k_1}{n} \sum_{i=1}^{n} \nu_i^2 \right) V$$

(86)

Equating this to $B/2$ and grouping the coefficients for $U$ and $V$ leads to the linear system

$$\begin{bmatrix}
\frac{1}{n} \sum_{i=1}^{n} \mu_i^2 & \frac{1}{n} \sum_{i=1}^{n} \mu_i \nu_i \\
\frac{1}{n} \sum_{i=1}^{n} \mu_i \nu_i & \frac{1}{n} \sum_{i=1}^{n} \nu_i^2
\end{bmatrix}
\begin{bmatrix}
k_0 \\
k_1
\end{bmatrix}
= \frac{1}{2}
\begin{bmatrix}
\frac{1}{n} \sum_{i=1}^{n} (\mu_i^2 + \nu_i^2) \mu_i \\
\frac{1}{n} \sum_{i=1}^{n} (\mu_i^2 + \nu_i^2) \nu_i
\end{bmatrix}$$

(87)

The coefficient matrix is the covariance matrix of the projection of the samples onto the plane perpendicular to $W$. Intuitively, this matrix is invertible as long as the projections do not lie on a line. If the matrix is singular (or nearly singular numerically), the original samples lie on a plane (or nearly lie on a plane numerically). They are not fitted well by a cylinder or, if you prefer, they are fitted by a cylinder with infinite radius.

The matrix system of Equation (87) has solution

$$\begin{bmatrix}
k_0 \\
k_1
\end{bmatrix}
= \frac{1}{2}
\begin{bmatrix}
\frac{1}{n} \sum_{i=1}^{n} \mu_i^2 - \frac{1}{n} \sum_{i=1}^{n} \mu_i \nu_i \\
\frac{1}{n} \sum_{i=1}^{n} \nu_i^2 - \frac{1}{n} \sum_{i=1}^{n} \mu_i \nu_i
\end{bmatrix}
\begin{bmatrix}
\frac{1}{n} \sum_{i=1}^{n} (\mu_i^2 + \nu_i^2) \mu_i \\
\frac{1}{n} \sum_{i=1}^{n} (\mu_i^2 + \nu_i^2) \nu_i
\end{bmatrix}$$

(88)

which produces the cylinder center $PC = k_0 U + k_1 V$; use this instead of $C$ in Equation (74).
Although the solution appears to depend on the choice of $U$ and $V$, it does not. Let $W = (w_0, w_1, w_2)$ and define the skew symmetric matrix

$$S = \begin{bmatrix} 0 & -w_2 & w_1 \\ w_2 & 0 & -w_0 \\ -w_1 & w_0 & 0 \end{bmatrix} \quad (89)$$

By definition of skew symmetry, $S^T = -S$. This matrix represents the cross product operation: $S\xi = W \times \xi$ for any vector $\xi$. Because $\{U, V, W\}$ is a right-handed orthonormal set, it follows that $SU = V$ and $SV = -U$. It can be shown also that $S = VU^T - UV^T$. Define matrix $\hat{A}$ by

$$\hat{A} = \left(\frac{1}{n} \sum_{i=1}^{n} \nu_i^2\right)UU^T - \left(\frac{1}{n} \sum_{i=1}^{n} \mu_i \nu_i\right) (UV^T + VU^T) + \left(\frac{1}{n} \sum_{i=1}^{n} \mu_i^2\right)VV^T = SAS^T \quad (90)$$

Effectively, this generates a $2 \times 2$ matrix that is the adjugate of the $2 \times 2$ matrix representing $A$. It has the property

$$\hat{A}A = \delta P, \quad \delta = \sum_{i=1}^{n} \mu_i^2 \sum_{i=1}^{n} \nu_i^2 - \left(\sum_{i=1}^{n} \mu_i \nu_i\right)^2 \quad (91)$$

The trace of a matrix is the sum of the diagonal entries. Observe that $\text{Trace}(P) = 2$ because $|W|^2 = 1$. Taking the trace of $\hat{A}A = \delta P$, we obtain $2\delta = \text{Trace}(\hat{A}A)$. The cylinder center is obtained by multiplying $A(PC) = B/2$ by $\hat{A}$, using the definitions in equation (83) and using equation (91),

$$PC = \frac{\hat{A}}{\text{Trace}(\hat{A}A)} \left(\frac{1}{n} \sum_{i=1}^{n} (X_i^T P X_i) P X_i\right) = \frac{\hat{A}}{\text{Trace}(\hat{A}A)} \left(\frac{1}{n} \sum_{i=1}^{n} (X_i^T P X_i) X_i\right) \quad (92)$$

where the last equality uses $\hat{A}P = \hat{A}$ because $S^T P = S^T$. Equation (92) is independent of $U$ and $V$ but dependent on $W$.

### 7.5 An Equation for the Direction

Let the direction be parameterized as $W(s) = (w_0(s), w_1(s), w_2(s))$, where $s$ is a 2-dimensional parameter. For example, spherical coordinates is such a parameterization: $W = (\cos s_0 \sin s_1, \sin s_0 \sin s_1, \cos s_1)$ for $s_0 \in [0, 2\pi]$ and $s_1 \in [0, \pi/2]$, where $w_2(s_0, s_1) \geq 0$. The partial derivatives of $E$ are

$$\frac{\partial E}{\partial s_k} = 2 \sum_{i=1}^{n} (v_i^2 - r^2)(C - X_i)^T \frac{\partial P}{\partial s_k} (C - X_i) \quad (93)$$

Solving $\partial E/\partial s_k = 0$ in closed form is not tractable. It is possible to generate a system of polynomial equations in the components of $W$, use elimination theory to obtain a polynomial in one variable, and then find its roots. This approach is generally tedious and not robust numerically.

Alternatively, we can skip root finding for $\partial E/\partial s_k = 0$, instead substituting Equations (80) and (92) directly into the error function $E/n = \frac{1}{n} \sum_{i=1}^{n} (v_i^2 - r^2)^2$ to obtain a nonnegative function,

$$G(W) = \frac{1}{n} \sum_{i=1}^{n} \left[ X_i^T P X_i - \frac{1}{n} \sum_{j=1}^{n} X_j^T P X_j - 2X_i^T \frac{\hat{A}}{\text{Trace}(\hat{A}A)} \left(\frac{1}{n} \sum_{j=1}^{n} (X_j^T P X_j) X_j\right) \right]^2 \quad (94)$$

34
A numerical algorithm for locating the minimum of \( G \) can be used. Or, as is shown in the sample code, the domain for \( (s_0, s_1) \) may be partitioned into samples at which \( G \) is evaluated. The sample producing the minimum \( G \)-value determines a reasonable direction \( W \). The center \( C \) and squared radius \( r^2 \) are inherent in the evaluation of \( G \), so in the end we have a fitted cylinder. The evaluations of \( G \) are expensive for a large number of samples: equation (94) contains summations in a term that is then squared, followed by another summation.

Some algebraic manipulation lead to encapsulating the summations, allowing us to precompute the summations and represent \( G(W) \) as a rational polynomial of the components of \( W \). This approach increases the performance on the CPU. It also allows an efficient implementation for massively parallel performance on the GPU—one GPU thread per direction vector that is sampled from a hemisphere.

The projection matrix \( P \) is determined by its upper-triangular elements \( p = (p_{00}, p_{01}, p_{02}, p_{11}, p_{12}, p_{22}) \). We can write the following, where \( p \) is represented as a \( 6 \times 1 \) vector,

\[
X^T_i P X_i - \frac{1}{n} \sum_{j=1}^{n} X^T_j P X_j = p \cdot (\xi_i - \mu) = p \cdot \delta_i
\]  

(95)

The \( 6 \times 1 \) vectors \( \xi_i, \mu \) and \( \delta_i \) are defined next (written as 6-tuples). As a 3-tuple, let \( X_i = (x_i, y_i, z_i) \),

\[
\xi_i = (x_i^2, 2x_i y_i, 2x_i z_i, y_i^2, 2y_i z_i, z_i^2), \quad \mu = \frac{1}{n} \sum_{i=1}^{n} \xi_i, \quad \delta_i = \xi_i - \mu
\]  

(96)

We can also write

\[
\frac{1}{n} \sum_{j=1}^{n} \left( X^T_j P X_j \right) X_j = \left( \frac{1}{n} \sum_{j=1}^{n} X_j \xi_j^T \right) p = \left( \frac{1}{n} \sum_{j=1}^{n} X_j \delta_j^T \right) p
\]  

(97)

The last equality is true because \( \sum_{j=1}^{n} X_j = 0 \) implies \( \sum_{j=1}^{n} X_j \mu^T = 0 \). Define

\[
Q = A / \text{Trace}(A^T A), \quad F_0 = \frac{1}{n} \sum_{j=1}^{n} X_j X_j^T, \quad F_1 = \frac{1}{n} \sum_{j=1}^{n} X_j \delta_j^T, \quad F_2 = \frac{1}{n} \sum_{j=1}^{n} \delta_j \delta_j^T
\]  

(98)

where \( Q \) and \( F_0 \) are \( 3 \times 3 \), \( F_1 \) is \( 3 \times 6 \) and \( F_2 \) is \( 6 \times 6 \); then

\[
G(W) = \frac{1}{n} \sum_{i=1}^{n} \left[ p^T \delta_i - 2X^T_i Q F_1 p \right]^2
\]

\[
= \frac{1}{n} \sum_{i=1}^{n} \left[ (p^T \delta_i)^2 - 4(p^T \delta_i) \left( X^T_i Q F_1 p \right) + 4\left( X^T_i Q F_1 p \right)^2 \right]
\]  

(99)

The precomputations for the input samples \( \{Y_i\}_{i=1}^{n} \) is the following and must be done so in the order specified. These steps are independent of direction vectors \( W \).

1. Compute \( A = \frac{1}{n} \left( \sum_{i=1}^{n} Y_i \right) \).
2. Compute \( X_i = Y_i - A \) for all \( i \).
3. Compute \( \mu = \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1}^{n} (x_i^2, 2x_i y_i, 2x_i z_i, y_i^2, 2y_i z_i, z_i^2), \delta_i = (x_i^2, 2x_i y_i, 2x_i z_i, y_i^2, 2y_i z_i, z_i^2) - \mu \) for all \( i \).
4. Compute \( F_0 = \frac{1}{n} \sum_{i=1}^{n} X_i X_i^T \), \( F_1 = \frac{1}{n} \sum_{i=1}^{n} X_i \delta_i^T \), \( F_2 = \frac{1}{n} \sum_{i=1}^{n} \delta_i \delta_i^T \).

For each specified direction \( W \), do the following steps.

1. Compute the projection matrix \( P = I - WW^T \) and the skew-symmetric matrix \( S \).
2. Compute \( A = PF_0 P \), \( \hat{A} = SAS^T \), \( \hat{A}A \), \( \text{Trace}(\hat{A}A) \).
3. Compute \( Q = \hat{A}/\text{Trace}(\hat{A}A) \).
4. Store the upper-triangular entries of \( P \) in \( p \).
5. Compute \( \alpha = F_1 p \) and \( \beta = Q \alpha \).
6. Compute \( G = p^T F_2 p - 4\alpha^T \beta + 4\beta^T F_0 \beta \).
7. The corresponding center is \( PC = \beta \).
8. The corresponding squared radius is \( r^2 = \frac{1}{n} \sum_{i=1}^{n} r_i^2 \) where \( r_i^2 = (PC - PX_i)^T(PC - PX_i) \). This factors to \( r^2 = p \cdot \mu + \beta^T \beta \).

The sample application that used equation (94) directly was really slow. On an Intel® Core™ i7-6700 CPU at 3.40 GHz, the single-threaded version for 10765 points required 129 seconds and the multithreaded version using 8 hyperthreads required 22 seconds. The evaluation of \( G \) using the precomputed summations is much faster. The single-threaded version required 85 milliseconds and the multithreaded version using 8 hyperthreads required 22 milliseconds.

7.6 Fitting for a Specified Direction

Although one may apply root-finding or minimization techniques to estimate the global minimum of \( E \), as shown previously, in practice it is possible first to obtain a good estimate for the direction \( W \). Using this direction, we may solve for \( C = PC \) in Equation (92) and then \( r^2 \) in Equation (79).

For example, suppose that the \( X_i \) are distributed approximately on a section of a cylinder so that the least-squares line that fits the data provides a good estimate for the direction \( W \). This vector is a unit-length eigenvector associated with the largest eigenvalue of the covariance matrix \( A = \sum_{i=1}^{n} X_i X_i^T \). We may use a numerical eigensolver to obtain \( W \), and then solve the aforementioned equations for the cylinder center and squared radius.

The distribution can be such that the estimated direction \( W \) from the covariance matrix is not good, as is shown in the experiments of the next section.

7.7 Pseudocode and Experiments

The simplest algorithm to implement involves the minimization of the function \( G \) in Equation (94). An implementation is shown in Listing 15.

---

36
Listing 15. Pseudocode for preprocessing the sample points. The output \( X[i] \) is the array of sample points translated by the average. The other outputs are \( \mu \) for \( \mu \), \( F_0 \) for \( F_0 \), \( F_1 \) for \( F_1 \) and \( F_2 \) for \( F_2 \). The pseudocode is also given for evaluating the function \( G(W) \) and generating the corresponding \( PC \) and \( r^2 \).

```c
void Preprocess(int n, Vector3 points[n], Vector3 X[n],
                Vector3 & average, Vector6 & mu, Matrix3x3 & F0, Matrix3x6 & F1, Matrix6x6 & F2)
{
    average = { 0, 0, 0 };
    for (int i = 0; i < n; ++i)
    {
        average += points[i];
    }
    average /= n;
    for (int i = 0; i < n; ++i)
    {
        X[i] = points[i] - average;
    }
    Vector6 zero = { 0, 0, 0, 0, 0, 0 };
    Vector6 products[n];
    MakeZero(products);
    mu = zero;
    for (int i = 0; i < n; ++i)
    {
        products[i][0] = X[i][0] * X[i][0];
        products[i][1] = X[i][0] * X[i][1];
        products[i][2] = X[i][0] * X[i][2];
        products[i][3] = X[i][1] * X[i][1];
        products[i][4] = X[i][1] * X[i][2];
        products[i][5] = X[i][2] * X[i][2];
        mu[0] += products[i][0];
        mu[1] += 2 * products[i][1];
        mu[2] += 2 * products[i][2];
        mu[3] += 2 * products[i][3];
        mu[4] += 2 * products[i][4];
        mu[5] += 2 * products[i][5];
    }
    mu /= n;
    MakeZero(F0);
    MakeZero(F1);
    MakeZero(F2);
    for (int i = 0; i < n; ++i)
    {
        Vector6 delta;
        delta[0] = products[i][0] - mu[0];
        delta[1] = 2 * products[i][1] - mu[1];
        F0(0, 0) += products[i][0];
        F0(0, 1) += products[i][1];
        F0(0, 2) += products[i][2];
        F0(1, 1) += products[i][3];
        F0(1, 2) += products[i][4];
        F0(2, 2) += products[i][5];
        F1 += OuterProduct(X[i], delta);
        F2 += OuterProduct(delta, delta);
    }
    F0 /= n;
    F0(1, 0) = F0(0, 1);
    F0(2, 0) = F0(0, 2);
    F0(2, 1) = F0(1, 2);
    F1 /= n;
    F2 /= n;
}
```

Real G(int n, Vector3 X[n], Vector3 mu, Matrix3x3 F0, Matrix3x6 F1, Matrix6x6 F2, Vector3 W,
        Vector3 & PC, Real & rSqr)
{
Matrix3x3 P = Matrix3x3::Identity() — OuterProduct(W, W); // P = I * W * W' 
// S = \{ \{0, -w2, w1\}, \{w2, 0, -w0\}, \{-w1, w0, 0\} \}. inner braces are rows
Matrix3x3 S(0, -W[2], W[1], W[2], 0, -W[0], -W[1], W[0], 0);
Matrix3x3 A = P * F0 * P;
Matrix3x3 hatA = -(S * A + S);
Matrix3x3 hatAA = hatA * hatA;
Real trace = Trace(hatAA);
Matrix3x3 Q = hatA / trace;
Vector3 p = \{ P(0, 0), P(0, 1), P(0, 2), P(1, 1), P(1, 2), P(2, 2) \};
Vector3 alpha = F1 * p;
Vector3 beta = Q * alpha;
Real error = (Dot(p, F2 * p) - 4 * Dot(alpha, beta) + 4 * Dot(beta, F0 * beta)) / n;
PC = beta;
rSqr = Dot(p, mu) + Dot(beta, beta);
return error;
}

The fitting is performed by searching a large number of directions \( W \), as shown in Listing 16.

Listing 16. Fitting a cylinder to a set of points.

// The \( \{X[i]\} \) are the points to be fit. The outputs rSqr, C, and W are the
// cylinder parameters. The function return value is the error function
// evaluated at the cylinder parameters.
Real FitCylinder (int n, Vector3 points[n], Real& rSqr, Vector3& C, Vector3& W)
{
    Vector3 X[n];
    Vector3 mu;
    Matrix3x3 F0;
    Matrix3x6 F1;
    Matrix6x6 F2;
    Preprocess(n, points, X, average, mu, F0, F1, F2);

    // Choose imax and jmax as desired for the level of granularity you
    // want for sampling W vectors on the hemisphere.
    Real minError = infinity;
    W = Vector3::Zero();
    C = Vector3::Zero();
    rSqr = 0;
    for (int j = 0; j < jmax; ++j)
    {
        Real phi = halfPi * j / jmax; // in [0,pi/2]
        Real cphi = cos(phi), snphi = sin(phi);
        for (int i = 0; i < imax; ++i)
        {
            Real theta = twoPi * i / imax; // in [0,2*pi]
            Real ctheta = cos(theta), stheta = sin(theta);
            Vector3 currentW(ctheta * cphi, sin(phi), ctheta * snphi, cphi);
            Vector3 currentC;
            Real currentRSqr;
            Real error = G(n, X, mu, F0, F1, F2, currentW, currentC, currentRSqr);
            if (error < minError)
            {
                minError = error;
                W = currentW;
                C = currentC;
                rSqr = currentRSqr;
            }
        }
    }

    // Translate the center to the original coordinate system.
    C += average;
    return minError;
}
The following experiments show how well the cylinder fitting works.

A regular lattice of $64 \times 65$ samples were chosen for a cylinder centered at the origin, with axis direction $(0,0,1)$, with radius 1, and height 4. The samples are $(\cos \theta_j, \sin \theta_j, z_{ij})$, where $\theta_j = 2\pi j/64$ and $z_{ij} = -2 + 4i/64$ for $0 \leq i \leq 64$ and $0 \leq j < 64$. The fitted center, radius, and axis direction are the actual ones (modulo numerical round-off errors). Figure 1 shows a rendering of the points (in black) and a wire frame of the fitted cylinder (in blue).

**Figure 1.** Fitting of samples on a cylinder ring that is cut perpendicular to the cylinder axis.

A lattice of samples was chosen for the same cylinder but the samples are skewed to lie on a cut that is not perpendicular to the cylinder axis. The samples are $(\cos \theta_j, \sin \theta_j, z_{ij})$, where $\theta_j = 2\pi j/64$ for $0 \leq j < 64$ and $z_{ij} = -b + \cos \theta_j + 2bi/64$ for $b = 1/4$ and $0 \leq i \leq 64$. The fitted center, radius, and axis direction are the actual ones (modulo numerical round-off errors). Figure 2 shows a rendering of the points (in black) and a wire frame of the fitted cylinder (in blue).
Figure 2. Fitting of samples on a cylinder ring that is cut skewed relative to the cylinder axis.

In this example, if you were to compute the covariance matrix of the samples and choose the cylinder axis direction to be the eigenvector in the direction of maximum variance, that direction is skewed relative to the original cylinder axis. The fitted parameters are (approximately) $\mathbf{W} = (0.699, 0, 0.715)$, $\mathbf{PC} = (0, 0, 0)$, and $r^2 = 0.511$. Figure 3 shows a rendering of the points (in black) and a wire frame of the fitted cylinder (in blue).
Figure 3. Fitting of samples on a cylinder ring that is cut skewed relative to the cylinder axis. The direction \( W \) was chosen to be an eigenvector corresponding to the maximum eigenvalue of the covariance matrix of the samples.

You can see that the fitted cylinder is not a good approximation to the points.

Figure 4 shows a point cloud generated from a DIC file (data set courtesy of Carolina Lavecchia) and the fitted cylinder. The data set has nearly 11000 points.
Figure 4. A view of a fitted point cloud.

Figure 5 shows a different view of the point cloud and cylinder.
7.8 Fitting a Cylinder to a Triangle Mesh

Imagine having a triangle mesh that approximates a portion of an infinite cylinder. When the triangles have small area and have normal vectors perpendicular to the cylinder axis, the projection of the triangles onto a plane perpendicular to the cylinder axis covers a region also of small area. If you were to project the cylinder itself onto the plane, you get a circle (not a disk) that covers a region of zero area. This suggests locating a direction $\mathbf{D}$ on the hemisphere of points $(x, y, z)$ with $z \geq 0$ for which the sum of areas of projections of the triangles of the mesh is minimized.

Let the mesh have $n$ points $\{\mathbf{P}_i\}_{i=0}^{n-1}$ and $m$ triangles, each a triple $(i_0, i_1, i_2)$ of indices into the points. Given a unit-length direction $\mathbf{D}$, let $\mathbf{U}$ and $\mathbf{V}$ be vectors for which $\{\mathbf{U}, \mathbf{V}, \mathbf{D}\}$ is a right-handed orthonormal set. For numerical robustness, compute the average $\mathbf{A} = \left(\sum_{i=0}^{n-1} \mathbf{P}_i\right)/n$ and replace $\mathbf{P}_i \leftarrow (\mathbf{P}_i - \mathbf{A})$. The points are projected onto a plane perpendicular to $\mathbf{D}$; they are $(u_i, v_i) = (\mathbf{U} \cdot \mathbf{P}_i, \mathbf{V} \cdot \mathbf{P}_i)$. Given the vertices of a
projected triangle, say \((u_0, v_0), (u_1, v_1)\) and \((u_2, v_2)\), the area of the projected triangle is

\[
A = \frac{1}{2} \left| (u_1 - u_0, v_1 - v_0) \cdot (u_2 - u_0, v_2 - v_0) \right|
\]

where \((u, v)\) = \((v, -u)\). The areas can be summed over all projected triangles, ignoring the overlap of projections; that is, the sum of areas is generally larger than the area of the union of the projections.

Pseudocode for a simple search over the hemisphere of directions to locate a minimum sum of areas is shown in Listing 17.

**Listing 17.** A simple search over the hemisphere of directions to locate a direction that minimizes the sum of areas of projected triangles. The factor 1/2 is ignored, so the minimum is over twice the area.

```cpp
struct Cylinder { Vector3 center, direction; Real radius, height; }
struct Circle { Vector2 center; Real radius; }

Cylinder FitMeshByCylinder(int numPoints, Vector3 points[], int numTriangles, int3 triangles[])
{
    // Translate the points so that the average is the origin (for numerical robustness).
    Vector3 localPoints[] = points[];
    Vector3 average = { 0, 0, 0 };
    for (int i = 0; i < numPoints; ++i)
    {
        average += points[i];
    }
    average /= numPoints;
    for (int i = 0; i < numPoints; ++i)
    {
        localPoints[i] = points[i] - average;
    }

    // Locate the direction D that minimizes the sum of the areas of the
    // projected triangles.
    Vector3 D;

        {
            V[i] = projections[triangles[t][i]];
            measure += abs(edge10[0] * edge20[1] - edge10[1] * edge20[0]);
        }
        return measure;
    }
}

8 Fitting a Cone to 3D Points

A double-sided cone has cone vertex $V$, unit-length cone axis direction $U$, and cone angle $\theta \in (0, \pi/2)$. The double-sided cone is defined algebraically by those points $X$ for which

$$U^T \left( \frac{X - V}{|X - V|} \right) = \cos(\theta) \quad (101)$$

The double-sided cone consists of two single-sided cones, the positive cone where $U^T(X - V) \geq 0$ and the negative cone where $U^T(X - V) \leq 0$. The algorithm described here is an attempt to fit a positive cone to a set of points.
A positive cone can be written as a quadratic equation by squaring the left-hand and right-hand sides of equation (101),
\[(X - V)^T \left( \cos(\theta)^2 I - UU^T \right) (X - V) = 0 \tag{102}\]
with the constraint that \(U^T(X - V) \geq 0\). Define \(\Delta = X - V\) and \(\hat{U} = U / \cos(\theta)\), so that \(|\hat{U}| > 1\) and
\[F(X; V, \hat{U}) = \Delta^T \left( I - \hat{U}U^T \right) \Delta = \Delta^T \Delta - (\hat{U}^T \Delta)^2 = 0 \tag{103}\]
The partial derivatives of \(F\) with respect to the cone parameters are
\[
\frac{\partial F}{\partial V} = -2 \left( \Delta - \left( \hat{U}^T \Delta \right) \hat{U} \right), \quad \frac{\partial F}{\partial U} = -2 \left( \hat{U}^T \Delta \right) \Delta \tag{104}\]
The nonlinear least-squares fitting of points \(\{X_i\}_{i=0}^{n-1}\) computes \(V\) and \(\hat{U}\) to minimize the error function
\[E(V, \hat{U}) = \frac{1}{n} \sum_{i=0}^{n-1} F(X_i; V, \hat{U})^2 \tag{105}\]
There are 6 independent parameters, the 3 components of \(V\) and the 3 components of \(\hat{U}\). Standard iterative minimizers such as the Gauss–Newton method or the Levenberg–Marquardt method can be used to estimate the parameters. The partial derivatives of \(E\) are needed to compute the Jacobian matrix. Define \(\Delta_i = X_i - V\). The partial derivatives of \(E(V, \hat{U})\) are
\[
\frac{\partial E}{\partial V} = 2 \sum_{i=0}^{n-1} F(X_i; V, \hat{U}) \frac{\partial F}{\partial V}(X_i; V, \hat{U}) = -\frac{4}{n} \sum_{i=0}^{n-1} \left( \Delta_i^T \Delta_i - \left( \hat{U}^T \Delta_i \right)^2 \right) \left( \Delta_i - \left( \hat{U}^T \Delta_i \right) \hat{U} \right) \tag{106}\]
and
\[
\frac{\partial E}{\partial U} = 2 \sum_{i=0}^{n-1} F(X_i; V, \hat{U}) \frac{\partial F}{\partial U}(X_i; V, \hat{U}) = -\frac{4}{n} \sum_{i=0}^{n-1} \left( \Delta_i^T \Delta_i - \left( \hat{U}^T \Delta_i \right)^2 \right) \left( \hat{U}^T \Delta_i \right) \Delta_i \tag{107}\]
The points to be fit should be distributed approximately uniformly near the positive cone. Generally, fitting a quadric surface to a set of points that purportedly live near a small patch of the quadric surface will not work well. The least-squares error function computes the errors only near the patch. The problem is ill conditioned in that small changes in the error function can cause large changes in the quadric surface parameters. Usually the collection of surfaces that fit the points have candidates that do not provide an accurate enough fit for an application’s needs.

An initial choice of parameters is required to start the iterative least-squares process for \(E(V, \hat{U})\). Without any application-specific knowledge about the sample points, an initial choice of parameters assumes the sample points are dense on a frustum of a cone. Various surface integrals are computed over that frustum, producing continuous formulations of important quantities. Those formulations are then replaced by discrete values based on the samples \(X_i\) that are to be fit by the cone. The integrals involve ratio expressions that are defined by
\[
\rho_n = \frac{\int_{h_0}^{h_1} h^{n-1} dh}{\int_{h_0}^{h_1} h dh} = \frac{\frac{1}{n} (h_1^n - h_0^n)}{\frac{1}{2} (h_1^2 - h_0^2)} \tag{108}\]
where \( h_0 \) is the minimum height for the frustum and \( h_1 \) is the maximum height for the frustum. The heights are measured in the direction of the cone axis.

The cone frustum surface is parameterized by

\[
P(h, \phi) = V + hU + (h \tan \theta)((\cos \phi)W_0 + (\sin \phi)W_1), \quad h \in [h_0, h_1], \quad \phi \in [0, 2\pi)
\]

where \( 0 \leq h_0 < h_1 \). The set \( \{U, W_0, W_1\} \) is a right-handed orthonormal basis for \( \mathbb{R}^3 \); that is, the vectors are unit length, mutually perpendicular, and \( U = W_0 \times W_1 \).

Define the rotation matrix \( R = [U \ W_0 \ W_1] \) whose columns are the specified basis vectors and define the \( 3 \times 1 \) vector

\[
Y(h, \phi) = \begin{bmatrix} h \\ h \tan \theta \cos \phi \\ h \tan \theta \sin \phi \end{bmatrix}
\]

The parameterization of the surface is concisely

\[
P(h, \phi) = V + RY(h, \phi)
\]

The surface integrals are formulated next for the parameterized cone. For notational convenience, I will use \( Y \) with the understanding that it depends on \( h \) and \( \phi \).

### 8.1 Estimation of the Cone Axis Direction

The element of surface area for the cone frustum surface is

\[
dA = \left| \frac{\partial P}{\partial h} \times \frac{\partial P}{\partial \phi} \right| dh d\phi = \left| [U + (\tan \theta)((\cos \phi)W_0 + (\sin \phi)W_1)] \times ((h \tan \theta)((-\sin \phi)W_0 + (\cos \phi)W_1)) \right| dh d\phi
\]

\[
= (h \tan \theta)\sqrt{\sin^2 \phi + \cos^2 \phi + \tan^2 \theta} dh d\phi
\]

\[
= (h \tan \theta)\sqrt{1 + \tan^2 \theta} dh d\phi
\]

The surface area of the cone frustum is

\[
A = \int_{h_0}^{h_1} \int_0^{2\pi} dA = \int_{h_0}^{h_1} \int_0^{2\pi} (h \tan \theta/ \cos \theta) dh d\phi = \frac{\pi \tan \theta}{\cos \theta} (h_1^2 - h_0^2)
\]
The average of $Y$ over the cone frustum surface is
\[
Y = \frac{1}{A} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} Y \, dA = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} Y \, h \, dh \, d\phi = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} \begin{bmatrix} 1 & \tan \theta \cos \phi & \tan \theta \sin \phi \\ \tan \theta \cos \phi & \tan^2 \theta \cos^2 \phi & \tan^2 \theta \sin \phi \cos \phi \\ \tan \theta \sin \phi & \tan^2 \theta \sin \phi \cos \phi & \tan^2 \theta \sin^2 \phi \end{bmatrix} h^2 \, dh \, d\phi
\]
\[
= \rho_3 \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}
\]

The average of $Y^T Y$ over the cone frustum surface is
\[
Y^T Y = \frac{1}{A} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} Y^T Y \, dA = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} Y^T Y \, h \, dh \, d\phi = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} (1 + \tan^2 \theta) h^3 \, dh \, d\phi
\]
\[
= \rho_4 \sec^2 \theta
\]

The average of $YY^T$ over the cone frustum surface is
\[
YY^T = \frac{1}{A} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} YY^T \, dA = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} YY^T \, h \, dh \, d\phi = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} \begin{bmatrix} 1 & \tan \theta \cos \phi & \tan \theta \sin \phi \\ \tan \theta \cos \phi & \tan^2 \theta \cos^2 \phi & \tan^2 \theta \sin \phi \cos \phi \\ \tan \theta \sin \phi & \tan^2 \theta \sin \phi \cos \phi & \tan^2 \theta \sin^2 \phi \end{bmatrix} h^3 \, dh \, d\phi
\]
\[
= \rho_4 \begin{bmatrix} 1, \frac{1}{2} \tan^2 \theta, \frac{1}{2} \tan^2 \theta \end{bmatrix}
\]

The average of $YY^T Y$ over the cone frustum surface is
\[
YY^T Y = \frac{1}{A} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} YY^T Y \, dA = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} YY^T Y \, h \, dh \, d\phi = \frac{1}{\pi(h_1^2 - h_0^2)} \int_{h_0}^{h_1} \int_{\phi=0}^{2\pi} (1 + \tan^2 \theta) \begin{bmatrix} 1 & \tan \theta \cos \phi \\ \tan \theta \cos \phi & \tan \theta \sin \phi \end{bmatrix} h^4 \, dh \, d\phi
\]
\[
= \rho_5 \sec^2 \theta
\]
If the point samples are nearly on a cone frustum, let the numerically computed eigenvalues be sorted as multiplicity 3. Selection of the first with multiplicity 1 and the second with multiplicity 2. For if we obtained such a result numerically, the other eigenvalue is the one associated with $U$; in particular, if the eigenvalues are nearly equal, it is not clear which eigenvector should be assigned to $U$. The next derivation provides the selection of $U$, which avoids the unreliable eigenvalue analysis.

The average of the points over the cone frustum surface is

$$\bar{C} = \frac{1}{A} \int_{h_0}^{h_1} \int_{0}^{2\pi} P(h, \phi) \, dh \, d\phi$$

$$= \frac{1}{\pi (\rho_1^2 - \rho_0^2)} \int_{h_0}^{h_1} \int_{0}^{2\pi} (V + hU + h \tan \theta (\cos \phi W_0 + \sin \phi W_1)) \, (h \tan \theta / \cos \theta) \, dh \, d\phi$$

$$= V + \rho_3 U$$

Define the difference $D = V - \bar{C} = -\rho_3 U$, in which case $P - \bar{C} = D + RY$. Define $Z = P - \bar{C}$ and define $i$ to be the $3 \times 1$ vector which as a 3-tuple is $(1, 0, 0)$. Observe that $Ri = U$. The average of $ZZ^T$ over the cone frustum surface is

$$\bar{ZZ}^T = \frac{1}{A} \int_{h_0}^{h_1} \int_{0}^{2\pi} ZZ^T \, dA$$

$$= \frac{1}{A} \int_{h_0}^{h_1} \int_{0}^{2\pi} \left( DD^T + DY^T R^T + RY D^T + RY Y^T R^T \right) \, dA$$

$$= DD^T + DY^T R^T + RY D^T + RY Y^T R^T$$

$$= (-\rho_3 U)(-\rho_3 U)^T + (-\rho_3 U)(\rho_3 i)^T R^T + R(\rho_3 i)(-\rho_3 U)^T$$

$$+ R(\rho_4 \text{Diag}(1/2 \tan^2 \theta, 1/2 \tan^2 \theta)) R^T$$

$$= (\rho_4 - \rho_3^2)UU^T + \frac{1}{2} \rho_4 \tan^2 \theta (W_0 W_0^T + W_1 W_1^T)$$

$$= R \text{Diag}(\rho_4 - \rho_3^2, \frac{1}{2} \rho_4 \tan^2 \theta, \frac{1}{2} \rho_4 \tan^2 \theta) R^T$$

The matrix $\bar{ZZ}^T$ is the covariance matrix of the cone frustum surface points and its eigendecomposition is given by the right-hand side of equation (119). In a numerical implementation, we need to identify which eigenvector output by the eigensolver corresponds to $U$. The covariance matrix of the point samples is used to estimate $\bar{ZZ}^T$. Numerically, we cannot expect two distinct eigenvalues $\lambda_1 = \rho_4 - \rho_3^2$ and $\lambda_2 = (\rho_4 \tan^2 \theta)/4$, the first with multiplicity 1 and the second with multiplicity 2. For if we obtained such a result numerically, selection of $U$ is trivial. Even theoretically we could have a problem when there is a single eigenvalue of multiplicity 3.

If the point samples are nearly on a cone frustum, let the numerically computed eigenvalues be sorted as $\lambda_1 \leq \lambda_2 \leq \lambda_3$. We could compute $\lambda_2 - \lambda_1$ and $\lambda_3 - \lambda_2$ and claim that the minimum difference is due to numerical rounding errors. The conclusion is that those two eigenvalues are theoretically a single eigenvalue. The other eigenvalue is the one associated with $U$. Some experiments showed that this is not a reliable way to select $U$; in particular, if the eigenvalues are nearly equal, it is not clear which eigenvector should be assigned to $U$. The next derivation provides the selection of $U$, which avoids the unreliable eigenvalue analysis.

The average of $ZZ^T$ over the cone frustum surface is

$$\bar{ZZ}^T = \frac{1}{A} \int_{h_0}^{h_1} \int_{0}^{2\pi} ZZ^T \, dA$$

$$= \frac{1}{A} \int_{h_0}^{h_1} \int_{0}^{2\pi} \left( (D^T D + (2DD^T R)Y + (Y^T Y) D (D^T D) RY + + (2RYY^T R^T) D + RYY^T Y) \right)$$

$$= (D^T D + (2DD^T R)Y + Y^T Y D + (D^T D) R Y + 2RYY^T R^T D + RYY^T Y$$

$$= (-\rho_3^2 + 2\rho_3^3 - \rho_3 \rho_4 \sec^2 \theta + \rho_3^3 - 2\rho_3 \rho_4 + \rho_5 \sec^2 \theta) U$$

$$= (2\rho_3(\rho_3^2 - \rho_4) + (\rho_5 - \rho_3 \rho_4) \sec^2 \theta) U$$

49
If we have good estimates for $\overline{C}$ and $\overline{ZZ^TZ}$, we can estimate the cone axis $U$ by normalizing the right-hand side of the last equality in equation (120). This has a pitfall, however, because the normalization does not take into account the sign of the coefficient of $U$ in that equation. It might be necessary to use the negative of the normalized vector; this is discussed as part of the next subsection.

8.2 Estimate of the Cone Vertex and Cone Angle

Let $\overline{C}$ be the average of the points $X_i$ and used as an estimate of $\overline{C}$. Let $Z_i = X_i - \overline{C}$. The estimate of $\overline{ZZ^T}Z$ is computed from the discrete set of points. The estimate is normalized to obtain $U$. Listing 18 has code to compute the estimates.

**Listing 18.** Code to generate estimates of $\overline{C}$ and $\overline{ZZ^T}Z$, the latter used to estimate $U$.

```cpp
template <typename T>
void ComputeEstimates(std::vector<Vector3<T>> const& X, Vector3<T>& C, Vector3<T>& U)
{
    C = {0, 0, 0};
    for (size_t i = 0; i < X.size(); ++i)
        C += X[i];
    C /= static_cast<T>(X.size());

    U = {0, 0, 0};
    for (size_t i = 0; i < X.size(); ++i)
    {
        Vector3<T> Z = X[i] - C; // Z[i]
        U += Z * Dot(Z, Z); // Z[i] * Z[i]^T * Z[i]
    }
    Normalize(U);
}
```

Listing 19 shows how to estimate the slope of a line on the cone surface, which determines the cone angle. During the process, it is determined whether $-U$ should be used instead of $U$. The listing also shows how to estimate the cone vertex once the cone angle and correct cone axis direction are known.

**Listing 19.** Code to estimate the cone angle and cone vertex. The code also determines whether to use $-U$ instead of $U$.

```cpp
template <typename T>
void InitializeCone(std::vector<Vector3<T>> const& X, Vector3<T>& V, Vector3<T>& U, T& angle)
{
    Vector3<T> C = {};
    ComputeEstimates(X, C, U);

    // Compute the signed heights of the points along the cone axis relative to C.
    // These are the projections of the points onto the line C+t*U. Also compute
    // the radial distances of the points from the line C+t*U.
    std::vector<Vector2<T>> hrPairs(X.size());
    T hMin = std::numeric_limits<T>::max(), hMax = hMin;
    for (size_t i = 0; i < X.size(); ++i)
    {
        Vector3<T> delta = X[i] - C;
        T h = Dot(U, delta);
        hrPairs[i].x = std::max(hMin, h); hMin = std::min(hMin, h);
    }
}
```
hMax = std::max(hMax, h);
Vector3 projection = delta — Dot(U, delta) * U;
T r = Length(projection);
hrPairs[i] = { h, r };}

// The radial distance is considered to be a function of height. Fit the
// (h,r) pairs with a line: r = rAverage * (h - hAverage);
ApprHeightLine2< double > fitter{};
fitter.Fit(hrPairs);
std::pair<Vector2<T>, Vector2<T>> parameters = fitter.GetParameters();
T hAverage = parameters.first[0];
T rAverage = parameters.first[1];
T hrSlope = parameters.second[0];

// If U is directed so that r increases as h increases, U is the correct
// cone axis estimate. However, if r decreases as h increases, -U is the
// correct cone axis estimate.
if (hrSlope < 0)
{
    U = -U;
    hrSlope = -hrSlope;
    std::swap(hMin, hMax);
    hMin = -hMin;
    hMax = -hMax;
}

// Compute the extreme radial distance values for the points.
T rMin = rAverage + hrSlope * (hMin - hAverage);
T rMax = rAverage + hrSlope * (hMax - hAverage);
T rRange = rMax - rMin;
T hRange = hMax - hMin;

// Using trigonometry and right triangles, compute the tangent
// function of the cone angle.
T tanAngle = rRange / hRange;
angle = std::atan2(rRange, hRange);

// Compute the cone vertex.
V = C - offset * U;

The initial cone estimate is used to start the minimizer iterations. The implementation is ApprCone3.h. The caller of the fitting function has the option to use the initial cone estimate provider here. If the application provides enough information to generate a user-created initial cone, the implementation also supports this.

9 Fitting a Paraboloid to 3D Points of the Form \((x, y, f(x, y))\)

Given a set of samples \(\{(x_i, y_i, z_i)\}_{i=1}^m\) and assuming that the true values lie on a paraboloid

\[
z = f(x, y) = p_1 x^2 + p_2 x y + p_3 y^2 + p_4 x + p_5 y + p_6 = P \cdot Q(x, y)
\] (121)

where \(P = (p_1, p_2, p_3, p_4, p_5, p_6)\) and \(Q(x, y) = (x^2, xy, y^2, x, y, 1)\), select \(P\) to minimize the sum of squared errors

\[
E(P) = \sum_{i=1}^m (P \cdot Q_i - z_i)^2
\] (122)

51
where \( Q_i = Q(x_i, y_i) \). The minimum occurs when the gradient of \( E \) is the zero vector,

\[
\nabla E = 2 \sum_{i=1}^{m} (P \cdot Q_i - z_i)Q_i = 0
\]

Some algebra converts this to a system of 6 equations in 6 unknowns:

\[
\left( \sum_{i=1}^{m} Q_i Q_i^T \right) P = \sum_{i=1}^{m} z_i Q_i
\]

The product \( Q_i Q_i^T \) is a product of the 6 \( \times \) 1 matrix \( Q_i \) with the 1 \( \times \) 6 matrix \( Q_i^T \), the result being a 6 \( \times \) 6 matrix.

Define the 6 \( \times \) 6 symmetric matrix \( A = \sum_{i=1}^{m} Q_i Q_i^T \) and the 6 \( \times \) 1 vector \( B = \sum_{i=1}^{m} z_i Q_i \). The choice for \( P \) is the solution to the linear system of equations \( AP = B \). The entries of \( A \) and \( B \) indicate summations over the appropriate product of variables. For example, \( s(x^3y) = \sum_{i=1}^{m} x_i^3 y_i \):

\[
\begin{bmatrix}
    s(x^4) & s(x^3y) & s(x^2y^2) & s(x^3) & s(x^2y) & s(x^2) \\
    s(x^3y) & s(x^2y^2) & s(xy^3) & s(x^2y) & s(xy^2) & s(xy) \\
    s(x^2y^2) & s(xy^3) & s(y^4) & s(xy^2) & s(y^3) & s(y^2) \\
    s(x^3) & s(x^2y) & s(xy^2) & s(x^2) & s(xy) & s(x) \\
    s(x^2y) & s(xy^2) & s(xy) & s(y^3) & s(y^2) & s(y) \\
    s(x^2) & s(xy) & s(y^2) & s(x) & s(y) & s(1)
\end{bmatrix}
\begin{bmatrix}
    p_1 \\
    p_2 \\
    p_3 \\
    p_4 \\
    p_5 \\
    p_6
\end{bmatrix}
= 
\begin{bmatrix}
    s(zx^2) \\
    s(zxy) \\
    s(zx^2) \\
    s(zx) \\
    s(z) \\
    s(z)
\end{bmatrix}
\]

An implementation is ApprParaboloid3.h.
